The molecular events responsible for the close association between *P. aeruginosa* and the lungs of patients with CF have not been defined fully. Inspissated secretions and dehydrated mucus decrease normal mucociliary clearance of organisms and facilitate chronic infection. Expression of increased numbers of asialylated glycolipid receptors for *P. aeruginosa* pili on the epithelium of the lung in such patients may predispose them to colonization.[158] Some studies suggest that naturally occurring airway antimicrobial peptides are functionally inhibited in the milieu of the CF lung.[159] After colonization, *P. aeruginosa* grows in microcolonies, forming biofilms within the airway.[160,161] The environment within the CF lung favors the proliferation of mucoid mutants of *P. aeruginosa* that produce large amounts of alginate exopolysaccharide, interfering with effective phagocytosis. After chronic infection is established, organisms are rarely, if ever, eradicated. Infection is endobronchial in location, with bacteria loosely enmeshed in a viscous layer of mucus that contains large amounts of cellular debris, neutrophil DNA, and actin. Histopathologic analysis shows areas of focal infection surrounded by neutrophils. Eventually, chronic infection, fibrosis, and loss of the normal pulmonary parenchyma result. Much of the observed pathology is due to the inflammatory response to *P. aeruginosa.*

Clinical Manifestations

Due to their inability to eradicate bacterial pathogens from the lower airways, patients with CF have chronic pulmonary symptoms, including persistent cough, expectoration of sputum, and progressive deterioration in pulmonary function. Acute episodes of clinical exacerbation are superimposed on chronic pulmonary symptoms. The wide variation in severity of underlying chronic manifestations makes it difficult to define a pulmonary exacerbation by clinical criteria alone.[162] Rather than new symptoms, an exacerbation more often is heralded by a quantitative change in ongoing symptoms, for example, an increase in frequency and intensity of cough or in the quantity and purulence of sputum. The acute and chronic symptoms are the result of vigorous inflammatory responses to endobronchial infection. Increased airway disease manifests as tachypnea and increased work of breathing (retractions, use of accessory respiratory muscles, and wheezing). Systemic manifestations of pulmonary exacerbation include malaise, myalgia, anorexia, weight loss, and (rarely) low-grade fever. Epidemiologic studies attempt to clarify the definition of acute exacerbation with the presence of four distinct clinical characteristics: new crackles, increased cough, increased sputum, and weight decline.[163] However, clinical responses to these symptoms, even when three or more are present, is inconsistent across providers at CF centers, complicating the interpretation of the proposed definition.[164]

Nonpulmonary symptoms of CF that can mimic infection include immune complex−mediated manifestations, such as vasculitic rashes[165] and arthritis.[166] In addition to pancreatic insufficiency, gastrointestinal manifestations include severe constipation, intestinal obstruction, and unrecognized or unusual presentations of acute appendicitis. Sinusitis secondary to nasal polyps is common.[167] Etiologic agents include the usual sinus pathogens plus organisms colonizing the lower airways in this population. In addition to episodes of acute and chronic infections, sinuses can serve as a reservoir for antibiotic-resistant organisms in patients undergoing lung transplantation.

Laboratory Findings

Decline in results of pulmonary function studies is the most accurate and objective indicator of pulmonary exacerbation. Unfortunately, most patients younger than 5 years cannot perform pulmonary function tests reproducibly, making the diagnosis of an exacerbation more difficult. The appearance of a new pulmonary infiltrate on a chest radiograph can be helpful; however, most pulmonary exacerbations, especially in patients with advanced disease, are unassociated with significant radiographic changes, probably because of the marked abnormalities present at baseline (Fig. 106.2).

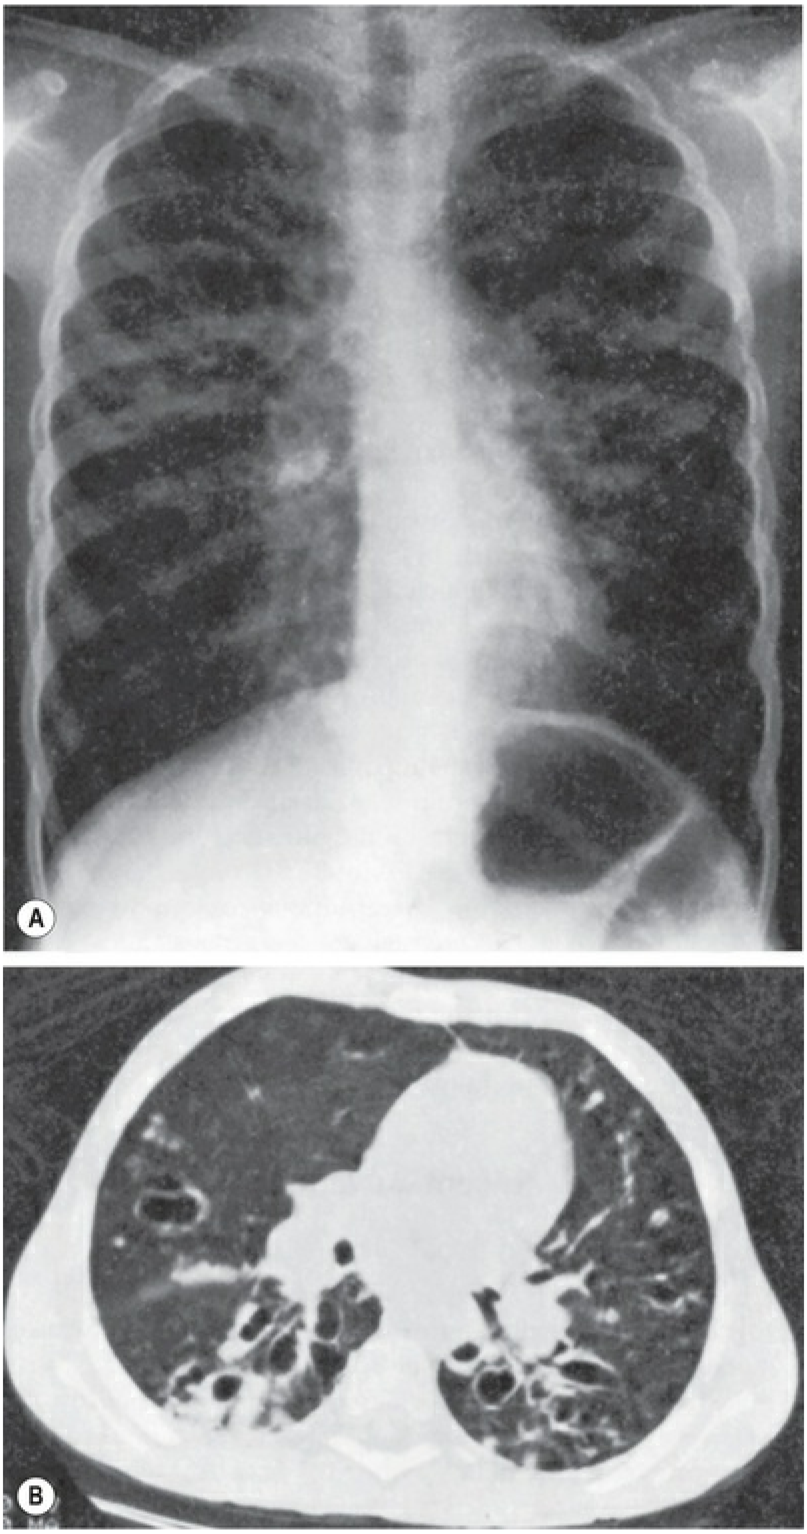

FIGURE 106.2 (A) Chest radiograph of a 14-year-old boy with cystic fibrosis demonstrating typical changes of hyperinflation, bronchial wall thickening, and areas of bronchiectasis and consolidation. (B) Computed

tomography demonstrates the magnitude of changes and diffuse nature of the pulmonary involvement.

Sputum culture can accurately identify the bacterial pathogens colonizing lower airway secretions.[168] Oropharyngeal culture (a suggested alternative in the nonexpectorating patient) is a relatively insensitive measure of lower airway pathogens.[169] Sputum induction is an alternative strategy, with organism recovery similar to bronchoalveolar lavage.[170,171] A technique combining the use of selective media and quantitative culture methods to identify infecting organisms in sputum also is used to evaluate therapeutic response.[172] This method circumvents the problem of rapidly growing mucoid strains of *P. aeruginosa,* which obscure the growth of more fastidious organisms such as *H. influenzae.*

Other laboratory studies helpful in defining a pulmonary exacerbation are white blood cell count with differential and measurements of acute-phase reactants, such as erythrocyte sedimentation rate and serum C-reactive protein level.[173] These tests have limited value without baseline measurements for comparison. BSI rarely is seen, except in a subpopulation of patients infected with *B. cepacia* complex, patients with an indwelling catheter, and immunosuppressed patients after lung transplantation.[174] Blood cultures are not indicated routinely in patients with CF unless they have one of these risk factors.

Management

The goal of acute and long-term treatment in CF is to prevent pulmonary damage from chronic infection and inflammation. Mainstays of therapy include nutritional support with pancreatic enzyme supplementation, chest physiotherapy to improve the drainage of pulmonary secretions, bronchodilator therapy to treat reactive airway disease, and antibiotic treatment to decrease bacterial density in the lungs. Antibiotic therapy in CF can take three forms: (1) early treatment of colonization (pre-emptive therapy); (2) suppression of chronic infection; and (3) treatment of acute pulmonary exacerbations.

Aggressive pre-emptive therapy for CF patients with their first *P. aeruginosa*–positive airway culture is the standard of care.[175] Several studies to decrease acquisition of chronic colonization or to eradicate first colonization of *P. aeruginosa* show clinical and microbiologic efficacy.[176–180] Danish groups have used ciprofloxacin in combination with inhaled colistin, whereas other studies have employed inhaled tobramycin and inhaled aztreonam.[181] After prolonged eradication, when *P. aeruginosa* did reappear, the organism most frequently was a new strain.[176,178]

The role of suppressive therapy in individuals with chronic *P. aeruginosa* infections also has been demonstrated, using antibiotics that may or may not have in vitro or in vivo antibacterial activity. Tobramycin has been used parenterally in pulmonary exacerbations for many years; most isolates of *P. aeruginosa* in patients with CF are susceptible. Use of high-dose inhaled tobramycin is associated with improvement in pulmonary function, decrease in the risk for hospitalization, and reduction in *P. aeruginosa* density in sputum without detectable ototoxicity or nephrotoxicity. Although a substantially higher rate of tobramycin resistance does not appear in individual studies,[182] resistance rates for tobramycin are increasing in longitudinal cohorts studied.[129,176–180] More recently, inhaled aztreonam lysinate has been shown to be safe and efficacious in CF, and its availability has resulted in increased use of combination inhaled therapy.[183,184] Several randomized controlled trials of treatment with oral azithromycin, a macrolide agent with anti-inflammatory properties, to which *P. aeruginosa* routinely is resistant in vitro, have demonstrated clinical improvement in lung function, body weight, number of exacerbations, and quality of life, but without a decrease in sputum bacterial density.[185–187]

Optimal antibiotic management of pulmonary exacerbations depends on knowledge of each patient's recent sputum bacteriology and susceptibility test results. Most often, two drugs with antipseudomonal activity are given—typically a β-lactam agent or fluoroquinolone plus an aminoglycoside.[188] Because of the potential for the induction of expression of the *Pseudomonas* chromosomal β-lactamase, combinations comprising two β-lactam agents generally are avoided. Late in the course of disease, multidrug-resistant strains are isolated frequently. Of note, in a controlled clinical trial in subjects with clinical exacerbations, antibiotic therapy directed by combination susceptibility (“synergy”) testing of *P. aeruginosa, B. cepacia* complex, *S. maltophilia,* and *A. xylosoxidans* did not result in better clinical or bacteriologic outcomes compared with therapy directed by standard testing.[189] Similar results were reported for therapy based on biofilm susceptibility testing.[190]

Several problems make the selection and use of antibiotics in patients with CF challenging. Chronic inflammation in the lung and localization of infection in the lumen of the airway make achievement of adequate levels of bioactive drug at the site of the infection difficult. The lack of a microbiologic end point for treating infections (organisms are never eradicated) makes definition of antibiotic resistance problematic. The differences in antibiotic pharmacokinetics identified in individuals with CF require the modification of drug dosing because the clearance of many drugs is high compared with that in unaffected controls.[191–193]

Recombinant human deoxyribonuclease has been demonstrated to improve pulmonary function and decrease the frequency of pulmonary exacerbations in patients with CF.[194] Improved mucociliary clearance results from lysis of the high concentrations of leukocyte DNA in the sputum of such patients.[195] Nebulized hypertonic saline, shown to improve mucociliary clearance, also has been demonstrated in short-term trials to improve mucociliary clearance, but is not recommended routinely in management.[196]

Bilateral lung transplantation is a potential life-extending therapy for selected patients with end-stage pulmonary disease. However, infectious complications caused by multidrug-resistant bacteria and fungi are a serious posttransplantation problem given the immunosuppression required for transplantation.[137] Although infected lungs are removed, colonization of upper respiratory and gastrointestinal tracts persists. Bronchiolitis obliterans also is a potentially fatal complication of transplantation.

Recent Advances

Investigational efforts in CF have been divided between anti-infective or anti-inflammatory strategies and potentially curative therapies. Aerosol administration of antimicrobial agents in addition to tobramycin and aztreonam is potentially advantageous because high concentrations of drug can be delivered directly to the site of infection while avoiding toxicity. The potential role of anti-inflammatory medications, including corticosteroids and ibuprofen, has been demonstrated in well-controlled clinical trials, although treatment with systemic corticosteroids has unacceptable side effects.[197,198] Other anti-inflammatory strategies currently being examined include inhibitors of proinflammatory mediators, anti-inflammatory cytokines, modulators of proinflammatory signaling cascades, antioxidants, and protease inhibitors.[199]

Potentially curative therapies for CF include gene therapy and pharmacologic approaches to correct the phenotype resulting from mutant CFTR. Although many CF-associated gene mutations have been identified, and administration of CFTR cyclic DNA to humans can complement the defect in vivo, the development of effective vectors to deliver the gene to the appropriate target cells and maintain its expression is challenging.[200,201] Another therapeutic strategy is the use of agents that restore activity of the mutant gene product such as CFTR potentiators, drugs that target protein folding and trafficking, and agents that induce translational read-through of stop codons and other nonsense mutations.[202] Recently, a CFTR potentiator, ivacaftor, was approved for use in CF patients 6 years and older with 1 of 10 specific CF mutations.[203] Additional studies using ivacaftor in combination with another CFTR ion transport corrector, lumacaftor, have shown promise for patients with the more common ΔF508 CFTR mutation.[204]

Prevention

Approaches to the prevention of *P. aeruginosa* colonization have included the aggressive use of prophylactic antibiotics and the development of antipseudomonal vaccines for use in noncolonized patients. Preliminary studies of at least two different vaccines against *P. aeruginosa* demonstrated safety and immunogenicity[205,206]; long-term follow-up of the polyvalent conjugate vaccine in 26 young children demonstrated a longer time to *P. aeruginosa* infection and fewer chronic infections in the study group compared with matched controls.[207]

Patients with CF should receive all routine childhood and adolescent immunizations, including acellular pertussis, PCV, varicella-zoster, and inactivated influenza vaccine.[208] In addition, their families should receive acellular pertussis and annual influenza vaccine because of the high rate of morbidity associated with these infections in CF patients.[143,147] There is no specific recommendation for routine administration of PPSV23 in patients with CF; however, a single dose of PPSV23 is recommended at 2 years or older for any immunocompetent child with chronic illness (including chronic lung disease).[49]

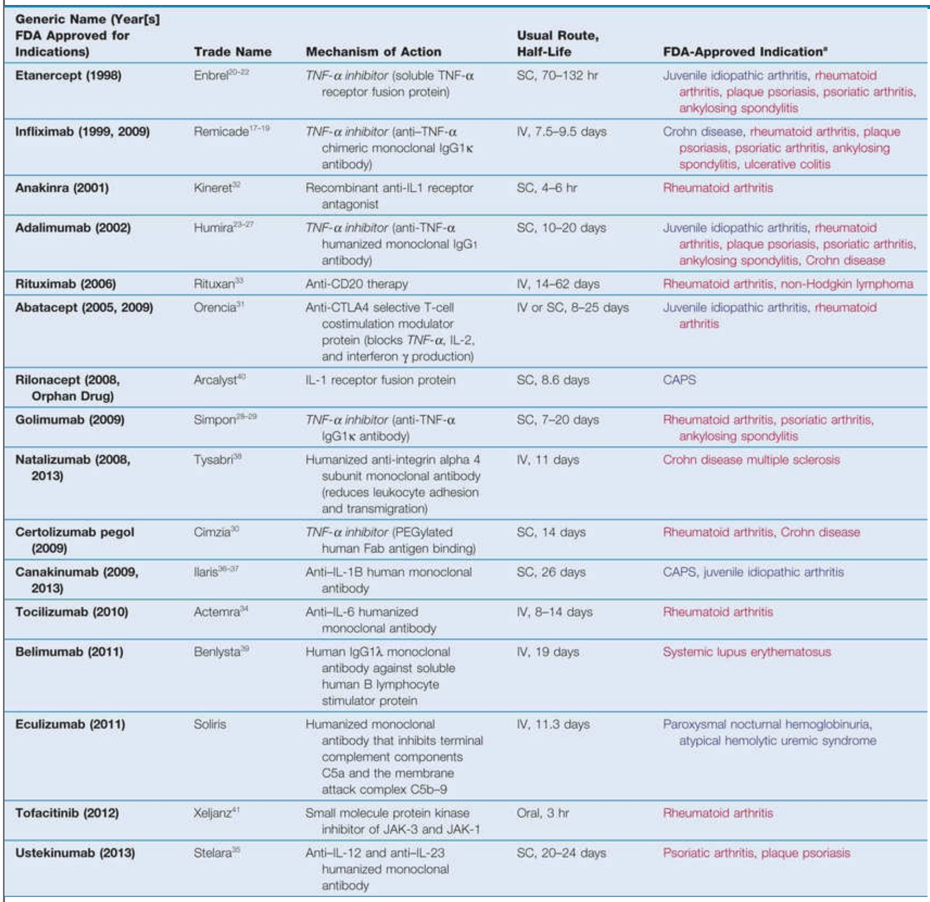
Infections Related to Biologic Modifier Therapy

H. Dele Davies

Biologic response modifiers (BRMs) have been developed to modify host immune responses, such as cytokines, chemokines, and antibodies that naturally protect against infections, but have become pathologic. Synthetic BRMs generally target or mimic natural cytokines or inhibitors, including tumor necrosis factor-α (TNF-α); interleukin-6 (IL-6), IL-12, and IL-23; and the receptors for IL-1α and IL-1β, and are used to restore, boost, or dampen the host immune response. This chapter deals only with BRMs that are used to dampen the response in autoinflammatory and autoimmune conditions. Although highly effective in reducing the underlying symptoms of the targeted condition and associated disability, BRMs also can lead to immunosuppression that persists for weeks to months after therapy.[1] Consequently, many of these drugs have been associated with an increased risk for infection with certain viral and mycobacterial pathogens as well as some fungal, other bacterial, and intracellular pathogens.[2–4] Most of the data on effects of BRMs are from adults,[5–9] with recommendations for children primarily from small case series and cohort studies.[2,10–16] Table 107.1 summarizes the BRMs currently approved by the US Food and Drug Administration (FDA), including their mechanisms of action, routes of administration, half-lives, and indications.[17–41]

TABLE 107.1

FDA-Approved Biologic Response Modifiers and Indications



Generic Name (Year[s] FDA Approved for Indications)	Trade Name	Mechanism of Action	Usual Route, Half-Life	FDA-Approved Indication[a]
Etanercept (1998)	Enbrel[20–22]	*TNF-α inhibitor* (soluble TNF-α receptor fusion protein)	SC, 70–132 hr	Juvenile idiopathic arthritis, rheumatoid arthritis, plaque psoriasis, psoriatic arthritis, ankylosing spondylitis
Infliximab (1999, 2009)	Remicade[17–19]	*TNF-α inhibitor* (anti–TNF-α chimeric monoclonal IgG1κ antibody)	IV, 7.5–9.5 days	Crohn disease, rheumatoid arthritis, plaque psoriasis, psoriatic arthritis, ankylosing spondylitis, ulcerative colitis
Anakinra (2001)	Kineret[32]	Recombinant anti-IL1 receptor antagonist	SC, 4–6 hr	Rheumatoid arthritis
Adalimumab (2002)	Humira[23–27]	*TNF-α inhibitor* (anti-TNF-α humanized monoclonal IgG1 antibody)	SC, 10–20 days	Juvenile idiopathic arthritis, rheumatoid arthritis, plaque psoriasis, psoriatic arthritis, ankylosing spondylitis, Crohn disease
Rituximab (2006)	Rituxan[33]	Anti-CD20 therapy	IV, 14–62 days	Rheumatoid arthritis, non-Hodgkin lymphoma
Abatacept (2005, 2009)	Orencia[31]	Anti-CTLA4 selective T-cell costimulation modulator protein (blocks *TNF-α*, IL-2, and interferon γ production)	IV or SC, 8–25 days	Juvenile idiopathic arthritis, rheumatoid arthritis
Rilonacept (2008, Orphan Drug)	Arcalyst[40]	IL-1 receptor fusion protein	SC, 8.6 days	CAPS
Golimumab (2009)	Simpon[28–29]	*TNF-α inhibitor* (anti-TNF-α IgG1κ antibody)	SC, 7–20 days	Rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis
Natalizumab (2008, 2013)	Tysabri[38]	Humanized anti-integrin alpha 4 subunit monoclonal antibody (reduces leukocyte adhesion and transmigration)	IV, 11 days	Crohn disease multiple sclerosis
Certolizumab pegol (2009)	Cimzia[30]	*TNF-α inhibitor* (PEGylated human Fab antigen binding)	SC, 14 days	Rheumatoid arthritis, Crohn disease
Canakinumab (2009, 2013)	Ilaris[36–37]	Anti–IL-1B human monoclonal antibody	SC, 26 days	CAPS, juvenile idiopathic arthritis
Tocilizumab (2010)	Actemra[34]	Anti–IL-6 humanized monoclonal antibody	IV, 8–14 days	Rheumatoid arthritis
Belimumab (2011)	Benlysta[39]	Human IgG1λ monoclonal antibody against soluble human B lymphocyte stimulator protein	IV, 19 days	Systemic lupus erythematosus
Eculizumab (2011)	Soliris	Humanized monoclonal antibody that inhibits terminal complement components C5a and the membrane attack complex C5b-9	IV, 11.3 days	Paroxysmal nocturnal hemoglobinuria, atypical hemolytic uremic syndrome
Tofacitinib (2012)	Xeljanz[41]	Small molecule protein kinase inhibitor of JAK-3 and JAK-1	Oral, 3 hr	Rheumatoid arthritis
Ustekinumab (2013)	Stelara[35]	Anti–IL-12 and anti–IL-23 humanized monoclonal antibody	SC, 20–24 days	Psoriatic arthritis, plaque psoriasis

[a] FDA approved indication: for conditions in *purple*, safety and efficacy have been established in children <18 years; for indications in *red*, safety and efficacy have only been shown in adults. Infliximab, etanercept, and adalimumab have been used off-label for scleritis, but none is FDA approved for this condition.

CAPS, cryopyrin-associated periodic syndromes (consisting of familial cold autoinflammatory syndrome and Muckle-Wells syndrome); FDA, U.S. Food and Drug Administration; IV, intravenous; SC, subcutaneous.

Data are from references 17 to 41.

Infections Associated With Use of Biologic Response Modifiers

Overall Rate of Serious Infections

Use of BRMs has been associated with elevated risk for developing certain bacterial (especially mycobacterial), viral, and fungal infections. The increased risk for infection likely is also contributed to by the concomitant use of other immunosuppressive agents, such as corticosteroids and methotrexate, and the underlying inflammatory disease.[20,42,43]

A Cochrane review involving more than 60,000 (primarily adult) participants receiving 9 different BRMs (adalimumab, certolizumab, etanercept, golimumab, infliximab, anakinra, tocilizumab, abatacept, and rituximab) for treatment of either rheumatoid arthritis (RA) or cancer[44] showed an overall increased risk for serious infections (defined as associated with death, hospitalization, or use of intravenous antibiotics) with an odds ratio [OR] of 1.37 and 95% confidence interval [CI] of 1.04–1.82, compared with placebo recipients.[44] The highest risks were seen with certolizumab (OR, 4.75; 95% CI, 1.52–18.5) and anakinra (OR, 4.05; 95% CI, 1.22–16.8). The risk for reactivation of tuberculosis (TB) among patients receiving BRMs also was elevated compared with those receiving placebo. Eculizumab (Soliris) is a humanized monoclonal antibody used for the treatment of paroxysmal nocturnal hemoglobinuria and atypical hemolytic uremic syndrome. This drug inhibits terminal complement components and increases the risk for invasive meningococcal infection markedly, a risk not completely ameliorated by conjugate vaccine administration (www.soliris.net).

In pediatric studies, risk for nonmycobacterial infection among patients receiving a BRM (e.g., etanercept) is similar to risk in those receiving the BRM plus conventional disease-modifying antirheumatic drugs (DMARDs) such as methotrexate.[21,22,45–52] Infections in those receiving BRMs are primarily lower respiratory tract and gastrointestinal infections, sepsis, skin infections, and abscesses. Nonetheless, even though there is no clear evidence of increased risk for nonmycobacterial infections in these patients compared with those receiving DMARDs alone, case reports of sepsis and even death among patients receiving a BRM have warranted vigilance and caution when using a BRM in a patient with active infection.

Rituximab-Associated Neutropenia

Rituximab-associated neutropenia is prolonged, lasting from 4 days to 1 year during or after completion of therapy, as reported primarily among adult patients being treated for lymphomas.[53–61] Neutropenia occurs in 0.02% to 6% of treated patients, but occurred in up to 25% in one series. In contrast to other BRMs in which the primary risk is for mycobacterial infections, rituximab is associated with fever and sepsis involving bacterial pathogens, especially *Pseudomonas* spp. Circulating antibodies against neutrophils have been postulated, but not proved as the cause.[61] Among 55 children treated with rituximab for juvenile idiopathic arthritis (JIA) after failure to respond to infliximab and other DMARDs, 17 (31%) developed neutropenia between weeks 6 and 28 of treatment. During a 96-week follow-up period among this cohort, 8 serious infections occurred—all lower respiratory tract infections, including *Pneumocystis jirovecii* and *Mycoplasma* pneumonia—but there were no cases of sepsis or neutropenia-associated fever without a focus.[60] Milder infections were noted, including ear, nose, and throat (14%) and skin (11%) infections and four cases of herpetic infections. The neutrophil count was less than 1500/mm^3 in 9 (16%) of the patients, 1000/mm^3 in 5 (9%) of the patients, and 500/mm^3 in 3 (6%) of the patients. All patients were treated with granulocyte-macrophage colony-stimulating factor (5 μg/kg/day). In 80% of patients, complete depletion of B lymphocytes (CD20$^+$ cells) occurred and persisted at low counts throughout the follow-up period. Serum immunoglobulin M (IgM) and IgG levels also were reduced below the age-related lower limits of normal in 11 patients (20%).

Specific Infections

Tuberculosis.

Use of TNF inhibitors has been associated with reactivation of infections caused by organisms in the *Mycobacterium tuberculosis* complex. In mouse models, TNF-α is known to contribute to granuloma formation and induces and maintains latency of *M. tuberculosis* infection[62]; blockage of TNF-α leads to failure to control bacillary growth and form protective granulomas.[63–66] In a Cochrane review of trials in which patients received BRMs or placebo,[44] the overall OR for Mtb reactivation in BRM recipients was 4.7 (95% CI, 1.2–18.6), with an absolute risk of 20 cases per 10,000 compared with 4 per 10,000 patients receiving placebo.

Studies in adults suggest that the risk for Mtb reactivation may be related to the class of TNF inhibitor, with TNF antibodies (e.g., infliximab and adalimumab) associated with the highest risk, and soluble TNF receptor antibodies (e.g., etanercept) appear to have the lowest risk.[67–70] Although risk appears lower with etanercept, the risk appears increased compared with the general population, but disease tends to be localized, although disseminated infection has been reported.[68,70–74]

In adult patients receiving BRMs, particularly TNF-α inhibitors, Mtb infection is associated with a substantial increase in extrapulmonary and disseminated disease, diagnoses that often require an invasive procedure.[75] In TNF-α–associated tuberculosis, 56% to 62% are reported to have extrapulmonary disease, and 24% to 28% have disseminated disease, compared with rates of 18% and 2%, respectively, in patients with non-HIV–related tuberculosis.[4,69] Because of the diminished host response, many patients do not develop granulomas. The median time to clinical disease varies by BRM—from 12 weeks (infliximab) to 30 weeks (adalimumab) to 46 weeks (etanercept).[74] It should be noted that the risk for Mtb reactivation associated with the underlying autoimmune or inflammatory conditions alone, without medications, is estimated to be twice that of the general population.[76]

Although data are limited for children, several case reports of Mtb reactivation are reported with use of TNF-α inhibitors.[36,68,77,78] However, screening and treating for latent tuberculosis infection (LTBI) before initiating BRM appears to reduce the risk for reactivation substantially. In 2210 adults treated worldwide with golimumab for a variety of rheumatologic conditions, none of 317 who were assessed and treated with isoniazid for LTBI developed disease, whereas 5 cases developed in patients not assessed and treated by week 52.[27]

Nontuberculous *Mycobacterium* Species.

Disease due to nontuberculous mycobacteria (NTM) has been reported to be twice as common as tuberculosis in adults receiving BRMs.[79–81] Pulmonary disease occurs most commonly (56%), but as with tuberculosis, 44% of patients come to attention with extrapulmonary disease. *Mycobacterium avium* complex is most commonly isolated. Absence of an accurate (sensitive and specific) screening test precludes baseline screening.[81]

Varicella-Zoster Virus.

Primary or reactivated varicella-zoster virus (VZV) infections frequently are reported as complications among patients receiving BRM.[2,46,49,82] These data support the importance of appropriate varicella immunization before immunosuppressive and BRM therapy and the recognition of exposures in patients taking any BRM. In at least one study involving the use of etanercept, all 3 patients with primary VZV infection recovered with acyclovir therapy and discontinuation of the BRM.[49]

Data on increased risk for herpes zoster are almost exclusively from adults.[83–86] Patients receiving monoclonal antibodies (infliximab or adalimumab) especially appear to have heightened risk for zoster compared with those receiving etanercept or DMARDs alone.[83] Encephalitis and meningitis attributable to herpes simples virus (HSV) and VZV also have been described in postmarketing surveillance of patients receiving natalizumab.[38]

Herpes Simplex.

Although uncommon, cases of HSV encephalitis, disseminated cutaneous HSV, and localized disease have reported complicating treatment with TNF-α inhibitors.[5,87–91] In one report, a girl with Crohn disease and relapsing HSV-1 peribuccal labialis was successfully treated with infliximab while receiving valacyclovir prophylaxis.[92]

Hepatitis B.

Patients receiving BRMs have an increased risk for hepatitis B virus (HBV) reactivation.[93,94] Patients who test positive for hepatitis B surface antigen (HBsAg) have the greatest (up to 39%) risk, but up to 5% of patients with hepatitis B core antibody (HBcAb) who are HBsAg negative (indicating immunity due to previous infection rather than vaccine) have had HBV reactivation up to 2 years after immunosuppression with BRMs.[95,96] In patients taking rituximab or TNF-α antagonists, the highest risk for reactivation is found among those with the lowest levels of hepatitis B surface antibody (HBsAb).[93,94]

Endemic Mycoses and Other Fungi.

Numerous cases and case series of fungal infections (*Aspergillus*,[89,91,97] *Coccidioides*,[98–100] *Histoplasma*, *Cryptococcus*, *Sporothrix*, and *Candida* spp.)[3,5,80,89,97,101–104] have been reported during treatment with BRMs. *Histoplasma* is the most common invasive fungal agent, reported 3 times more frequently than tuberculosis among recipients of BRMs.[3,80,102,103] Histoplasmosis and acute tuberculosis share symptoms, signs, (cough, fever, chills, night sweats, weight loss, and possible skin or mouth lesions), and chest radiographic findings, making it difficult yet critical to establish the correct diagnosis. Histoplasmosis generally manifests as fever of unknown origin due to disseminated disease in up to three fourths of patients and has high mortality (50%); pulmonary histoplasmosis is less common.[102] Nonspecific diagnostic clues include pancytopenia and elevated serum hepatic enzymes; definitive diagnosis requires antigen detection in the urine and serum or isolation in culture of bone marrow. Other fungal infections identified less commonly include *P. jirovecii* pneumonia (PCP), aspergillosis, and severe *Candida* spp. infections.[4]

Pneumocystis jirovecii and Rituximab Treatment.

P. jirovecii colonizes 16% to 29% of adults with systemic autoimmune inflammatory diseases.[105–107] Although PCP has been identified in patients receiving several BRMs,[108–110] rituximab (which depletes B lymphocytes that are crucial to control *P. jirovecii*) particularly is associated with increased risk for PCP.[111] There is no clear benefit of screening for PCP by use of induced sputum or of chemoprophylaxis for PCP in patients receiving rituximab.[106,112]

Human Immunodeficiency Virus.

There are no reports of increased rate of HIV infections among patients receiving BRMs.

Other Infections.

Opportunistic-type infections, including those due to cytomegalovirus, Epstein-Barr virus (EBV),[89] and *Listeria*[113–115] and *Legionella* spp.,[116,117] have been noted in case reports or case series during treatment with BRMs used alone or with other DMARDs. However, in one study of infliximab over 6 weeks to 5 years, there was no evidence of EBV or cytomegalovirus reactivation during treatment based on viral load or polymerase chain reaction testing.[118,119]

Considerations for Patients Before Initiation, During Use, and After Discontinuation of Biologic Response Modifier Therapy

General Precautions

Table 107.2 summarizes recommended screening and immunization practices for patients before initiating, during, and after discontinuation of BRM. Consideration of whether to defer BRMs in order to immunize against vaccine preventable diseases, or to delay immunizations, involves tradeoffs and should be made with the specialist managing the patient (e.g., gastroenterologist, rheumatologist, dermatologist). Nonetheless, application of some common principles can help minimize the risk for serious infections for patients receiving BRMs:

TABLE 107.2

Summary of Suggested Screening/Immunizations Before Initiating, During, and After Discontinuation of Biologic Response Modifier Therapy[a]

Before Initiating BRM[a]	
Thorough history	Document prior vaccines, antibody testing when indicated (routine antibody testing not recommended for varicella) Query about possible exposure and epidemiologic risk factors for histoplasmosis and coccidioidomycosis Query about history of recurrent HSV Consider serologic testing for Epstein-Barr virus Screen for past hepatitis B and determine need for vaccine (see Table 107.3)

Routine immunizations	Follow current AAP, CDC, and American Academy of Family Physician guidelines[b,132] Give recommended inactivated or subunit vaccines ≥2 weeks before initiation of BRM Consider safety of giving live virus vaccine(s); if appropriate, give ≥4 weeks before initiating BRM[122]
Tuberculosis	Test for latent tuberculosis and manage based on result (see reference 148 for algorithm)
During BRM[a]	
Routine immunizations	Should still receive routine inactivated, polysaccharide, recombinant, or subunit vaccine[b,c] Give annual inactivated influenza vaccine[122] Avoid live vaccines, unless under special circumstances with help of infectious diseases specialist[122]
Immunizing immunocompetent household contacts (before or during treatment)?	Follow AAP guidelines for immunizing household contacts of immunocompromised patients[122]
Risk for listeriosis	Avoid unpasteurized milk and milk products, uncooked meats[133]
Febrile or serious respiratory illness during BRM therapy	Consider stopping BRM and actively search for infections, including bacterial, mycobacterial, and opportunistic infections
After Discontinuation of BRM[a]	
Routine inactivated immunizations	Should receive routine inactivated, polysaccharide, recombinant, or subunit vaccine[b,c]
Live virus vaccines	See text and consult infectious diseases specialist for timing

[a] Guidance should be considered only as such. Each situation should be guided by clinical scenario and with the help of an infectious diseases consultant.

[b] If receiving/received eculizumab, should be given meningococcal conjugate vaccines (serogroup B as well as ACWY) as for high-risk patients (see Chapter 125).

[c] If receiving (received) rituximab, may respond adequately.

AAP, American Academy of Pediatrics; *BRM,* biologic response modifier; *CDC,* Centers for Disease Control and Prevention; *HSV,* herpes simplex virus.

- Consider all patients with new diagnoses of rheumatologic or immune-mediated conditions, such as Crohn disease or JIA, as current or future candidates for a BRM and screen for potential opportunistic infections *at the time of diagnosis* and before starting immunosuppressive agents.
- Do not give BRMs to patients during clinically significant acute infections.
- Exercise caution in prescribing BRMs to children receiving treatment for chronic infections, have a history of recurrent infections, or have underlying conditions that may predispose them to chronic infection (including HIV).[70]
- Consider potential opportunistic infections endemic in the

patient's area of residence (e.g., histoplasmosis, coccidioidomycoses) before starting a BRM, including determination of prior exposure and potential risk for reactivation or infection during treatment with the BRM.

- Withhold the BRM immediately if the patient develops symptoms suggestive of an opportunistic infection; aggressively seek confirmation of the diagnosis, appropriately manage the infection, and await resolution of symptoms.
- Monitor neutrophil counts weekly and measure serum immunoglobulin levels if there are recurrent ear, nose, or throat infections in patients receiving rituximab.

Managing Immunizations

Immunization Before Initiating Biologic Response Modifier Therapy.

All children planned to receive a BRM first should receive immunizations guided by current recommendations of expert organizations (see http://aapredbook.aappublications.org/site/resources/IZSchedule.pd
Recommendations include the following:

- Obtain a thorough immunization history and history of prior vaccine preventable disease. Consider specific antibody serologic testing when the history is inadequate, except for varicella, for which vaccination is the recommended course if there is adequate time for safe administration (4 weeks minimum) before initiating BRM.
- Administer inactivated vaccines at least 2 weeks before initiating BRM.
- Administer live virus vaccines (varicella; measles, mumps, and rubella [MMR]; rotavirus; live, attenuated influenza) at least 4 weeks before initiating BRM. Both MMR vaccine and a tuberculin skin test (TST) can be administered on the same day; otherwise, if MMR has been given, TST should be delayed for 4 to 6 weeks because of suppression of TST response by MMR vaccine.[121] Interpretation of TST is not affected by inactivated, toxoid, polysaccharide, or recombinant or subunit vaccines.

- *Do not* administer live virus vaccines to children who have underlying conditions that suppress the immune system (e.g., lupus) or who are receiving medications that suppress the immune system, except in very special circumstances.[122] Live virus vaccines should not be administered for at least 1 month after discontinuation in patients receiving high-dose corticosteroids (i.e., ≥2 mg/kg/day of prednisone or its equivalent, or ≥20 mg/day for those weighing more than 10 kg >14 days).[122]

Immunization During Biologic Response Modifier Therapy.

Responses to inactivated, polysaccharide, recombinant, or subunit vaccines, including the inactivated influenza vaccines, are reduced but adequate; inactivated vaccines should be given to patients receiving BRMs when indicated.[123–126] The possible exception is receipt of rituximab, which significantly impairs antibody response, especially for pneumococcal conjugate vaccines, during therapy and for up to 6 months after discontinuation.[127–131] Every effort should be made to immunize patients who will receive rituximab before commencement. To guide need for additional vaccine doses and to manage future exposures during BRM therapy, postimmunization serum antibody levels measured 4 to 6 weeks after immunization may be helpful.[122] Patients receiving BRMs or other immunosuppressive drugs during treatment should not be given live, attenuated influenza vaccine or other live vaccines because of risk for dissemination and adverse outcomes, except in special circumstances as recommended by an infectious diseases specialist.[122] Inactivated influenza vaccine should be administered annually.

Immunization After a Biologic Response Modifier Is Discontinued.

Data are insufficient currently to guide how soon live vaccine may be given after discontinuation of BRM.[122]

Immunizing Immunocompetent Household Contacts of Patients Receiving Biologic Response Modifiers.

Household members should all receive recommended inactivated vaccines following guidelines recommended by the American

Academy of Pediatrics for household contacts of immunocompromised patients.[122] Household contacts of people receiving BRM should not be given oral polio vaccine (no longer given in the United States). MMR, varicella, and rotavirus vaccines should be given to household contacts as recommended. Vaccine strain transmission is very low, and the disease associated with the virus is expected to be mild. If a household contact develops a vesicular rash after receipt of the varicella vaccine, separation of that contact from the BRM recipient may be prudent for the duration of the rash. Administration of varicella-zoster immune globulin is not indicated. Influenza vaccine should be given annually to all household contacts who are 6 months or older,[122] using any age-appropriate vaccine.

Evaluation and Treatment of *Mycobacterium tuberculosis* Infection

Screening for LTBI and treatment should be performed in all patients immediately after diagnosis of rheumatologic or inflammatory and autoimmune conditions for which BRM therapy may be needed regardless of risk factors and using the following principles[134–136]:

- Consider options for screening based on the clinical scenario. Use a TST or an interferon γ release assay (IGRA) or both. Either QuantiFERON-TB Gold in-tube assay (QFT; Cellestis/Qiagen, Carnegie, Australia) or the T-SPOT.*TB* assay (T-SPOT; Oxford Immunotec, Abingdon, United Kingdom) IGRA is acceptable.[136,137]
- If there are no risk factors for LTBI (prior history of TB, prior history of positive TST, history of exposure to someone with active TB, travel to an area with endemic TB in the past 12 months, or foreign-born patient or parents from area with endemic TB) and *no* symptoms suggestive of TB, choose baseline screening method based on age. In general, TST should be used to screen children younger than 5 years, while an IGRA should be used for children older than 5 years.[137]
- If *any risk factor* for LTBI is present or any symptom is suggestive of TB, test for LTBI with *both* the TST and an IGRA. If either test is positive, perform chest radiography (posteroanterior and lateral)

and begin appropriate treatment for either LTBI or TB disease (after further evaluation), depending on clinical and laboratory findings.[137] IGRA should not be relied on to test for LTBI in children younger than 2 years because of lack of data and high risk for progression to disease. IGRA can be considered in children 2 years and older, especially those who have received bacille Calmette-Guérin vaccine.[137]

- Query patients for TB symptoms and risk factors *each year*; routine annual TST or IGRA is not recommended.
- If change in risk or new symptoms suggestive of TB infection develop during BRM, further investigate and reassess risk (i.e., repeat both the TST and IGRA if the baseline was negative and perform chest radiography).
- Treat all patients with LTBI.[134,135]
- Withhold BRM and other DMARDs if active TB is suspected until infection is excluded or is under control. An infectious diseases specialist should guide isolation precautions and management, including considerations of risks for drug-resistant infection and presence of disseminated or extrapulmonary disease.[138]

Evaluation for Nontuberculous Mycobacteria and Fungi

No screening is recommended, but NTM should be considered in the differential diagnosis of patients taking BRMs for whom TB is being considered, or those with febrile illnesses, cervical or unexplained lymphadenitis, or other focal infections.

Both histoplasmosis and coccidioidomycosis have signs and symptoms that overlap substantially with tuberculosis; patients should be queried about possible exposure and epidemiologic risk factors.[102,104,139–141] Routine serologic screening is not indicated for histoplasmosis because up to 90% of persons living in a histoplasmosis belt will have acquired the fungus with self-resolving infection and positive serology before adulthood, and negative serology does not predict risk for development of histoplasmosis during therapy.[102] Similarly, residence in endemic geographic areas (e.g., southwestern United States and southern California) is a risk for developing coccidioidomycoses,[98,99,141–144] and certain racial groups (Filipino, Hispanic, black, American Indian, and Asian people), pregnant women during the third trimester, and women in the immediate postpartum period have heightened risk for severe disease. Invasive and disseminated disease occurs in about 2% of patients receiving BRM who reside in at-risk regions. For patients with signs or symptoms compatible with acute histoplasmosis[102,104,139,140] or coccidioidomycosis[98–100,142–144] during treatment, BRM should be withheld immediately and evaluation performed urgently (e.g., chest radiography and serologic, antigen detection, and culture tests).

Evaluation for Certain Viruses

Varicella-Zoster Virus and Herpes Simplex Virus.

Routine serologic testing should not be performed for VZV because of wide variability in the sensitivity of the assays in assessing immunity after VZV immunization. If there is doubt about immunity based on the history or inadequacy of records, the patient should be immunized (with the timing and other precautions discussed earlier for live vaccines).[145]

BRM therapy should be stopped immediately in patients suspected of having VZV or HSV infection and diagnosis sought using a combination of clinical, serologic, and polymerase chain reaction testing of skin lesions (i.e., vesicles or papules). Therapy should be initiated with acyclovir or valacyclovir pending confirmation of diagnosis. Prophylaxis with valacyclovir or acyclovir is considered in patients with recurrent HSV who are being considered for BRM therapy.

Epstein-Barr Virus.

Baseline serologic testing for EBV should be assessed at the time of diagnosis of the underlying rheumatologic condition and subsequent testing should be considered if the patient develops becomes symptomatic or has signs associated with EBV such as a mononucleosis-like illness or excessive fatigue.

Hepatitis B Virus.

Table 107.3 summarizes the approach to screening for previous hepatitis B infection before initiating BRM, based on the serology and immunization records, along with suggested management. Baseline serum hepatic enzyme levels should be obtained.[146–151] Patients recommended for immunization (those who are negative for HBsAg, HBcAb, and HBsAb or who are positive only for HBsAb positive) should be immunized with the first dose of hepatitis B vaccine at least 2 weeks before initiation of BRM.[1,152] The decision to give the full series of HBV vaccinations before starting BRM includes weighing benefits versus risks of delaying BRM.[125,153] It should be noted that a transiently positive serologic test result can occur after receipt of immune globulin intravenous. Regular monitoring (every 1–3 months, depending on underlying HBV infection) hepatic enzymes, HBsAg, hepatitis B core e antigen, and HBV DNA levels should be conducted for all patients considered at risk for HBV reactivation (chronic, resolved, or occult infection) and continued for at least 6 months after discontinuing BRM.

TABLE 107.3

Screening Tests for Hepatitis B Virus Infection, Interpretation, and Recommendations Before Biologic Response Modifier Therapy

HBV Infection	HBsAg	HBsAb	HBcAb	HBcIgM	Abnormal Lfts and/or Symptoms	Additional Testing	Management	Comm
Uninfected, nonimmune	−	−	−	−	−	−	Safely treat with BRM	Admin HBV vaccin before BRM therap
Vaccinated	−	+	−	−	−	−	Safely treat with BRM	For HB <10 mIU/m sugges HBV booste
Acute	+	−	+	+	+	−	Defer BRM therapy	
Chronic	+	−	+	−	+/−	HBeAg, HBeAb, HBV DNA	Treat with BRM in consultation with ID consultant or hepatologist	
Resolved	−	+	+	−	−	HBV DNA	Treat with BRM in consultation	

							with ID consultant or hepatologist	
Occult	−	−	+	−	−	HBV DNA	Treat with BRM in consultation with ID consultant or hepatologist	

HBcAb, hepatitis B core antibody; HBcIgM, hepatitis B core antibody; HBeAb, hepatitis B core antibody; HBeAg, hepatitis B core e antigen; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; ID, infectious disease; LFT, liver function test; *BRM,* biologic response modifier.

From Motaparthi K, Stanisic V, Van Voorhees AS, et al. From the Medical Board of the National Psoriasis Foundation: recommendations for screening for hepatitis B infection prior to initiating anti-tumor necrosis factor-alfa inhibitors or other immunosuppressive agents in patients with psoriasis. J Am Acad Dermatol 2014;70:178–186.

Key Points

Biologic Response Modifiers

- Biologic response–modifiers (BRMs) are effective for management of patients with a variety of autoimmune and inflammatory conditions but also can lead to immunosuppression that persists for weeks to months after discontinuation of therapy.

- BRMs are associated with an increased risk for acquisition or reactivation of some serious and opportunistic infections, especially *Mycobacterium tuberculosis*, nontuberculous mycobacteria, certain fungal and intracellular pathogens and viral infections, including hepatitis B.

- Screening, appropriate immunization, and anticipatory guidance are critical before initiating BRMs to reduce the risk for infection and disease and for negative outcomes from infections.

- In general, BRMs should be withheld when active infection is suspected or proved until adequately controlled.

Infectious Complications of Corticosteroid Therapy

Kari A. Simonsen, H. Dele Davies

Corticosteroids play a key role in the management of many neoplastic, autoimmune, allergic, and autoinflammatory disorders. Corticosteroids also sometimes are used for their lifesaving lympholytic and anti-inflammatory effect during infection, for example, to prevent airway obstruction during croup or Epstein-Barr virus–associated tonsillitis, or to dampen immune reconstitution inflammatory syndrome (IRIS) when treating pulmonary or brain infection in patients with acquired immunodeficiency syndrome (AIDS). Corticosteroid also is given almost universally after surgery on airway structures or before extubation. Despite widespread applications, utility is tempered by the occurrence of myriad adverse effects, including increased risk and severity of infections.

Corticosteroids can be either naturally produced or laboratory-synthesized hormones; glucocorticoids generally regulate inflammation and metabolism, whereas mineralocorticoids regulate water and sodium.[1] Glucocorticoids are highly lipid soluble and readily penetrate cell membranes, binding to a specific receptor present in all nucleated cells, which allows both anti-inflammatory and metabolic effects without specificity.[2] Corticosteroids generally are metabolized by the hepatic P450 system. Direct application to sites of inflammation (e.g., topical, inhaled, epidural) provides high local concentrations and bypasses rapid metabolism.[3]

Glucocorticoids exert anti-inflammatory effects through multiple mechanisms: reduction in circulating leukocyte populations, including neutrophils, lymphocytes, monocytes, eosinophils, and basophils; inhibition of production of cytokine and other proinflammatory molecules; inhibition of synthesis of interleukin-2 (IL-2) receptor; and reduction of expression of major histocompatibility complex (MHC) molecules on the surface of antigen-presenting cells, leading to suppression of immunologic response. With prolonged administration, cell-mediated immunity is suppressed.[4]

Initially, administration of a glucocorticoid causes a temporary increase in the peripheral circulation of neutrophils due to enhanced release from bone marrow and reduced migration from blood vessels. Ultimately, the peripheral leukocyte count declines because of migration of lymphocytes, monocytes, basophils, and eosinophils from the peripheral vasculature to the lymphoid tissues.[5] Neutrophil function and bactericidal activity are impaired at least in part owing to reduced adherence to vascular endothelium and diapedesis into interstitial spaces.[6]

Infectious Adverse Effects of Glucocorticoids

It is challenging to confirm a direct causal relationship between corticosteroid use and increased risk or severity of infection because of the wide range of underlying diseases for which corticosteroids are prescribed and the combination immunosuppressive therapies that many patients receive. Although much of available data are derived from observational studies in adults, the body of data in children suggest that extrapolation of effects to children is reasonable. Corticosteroids have been associated with increased risk for infection across multiple immunocompromised states as well as in previously immunocompetent hosts.[7,8] In a meta-analysis of adult and pediatric patients receiving corticosteroids, the relative risk (RR) for infectious complications was 1.6 (95% confidence interval [CI], 1.3–1.9; $P < 0.001$).[9] Confining analysis to adults taking daily doses of prednisone between 20 mg and 40 mg, the RR of infection was 2.1 (95% CI, 1.3–3.6): a pediatric subset analysis was not reported. Increased rates of infection were not seen in adult and pediatric patients given prednisone at daily doses of <10 mg or cumulative doses of <700 mg when analyzed together.[9] Thus higher doses of glucocorticoids and combination therapy with other immunosuppressive agents elevate the risk for infectious complications.[10] Excess risk or severity or infections caused by bacterial, fungal, viral, and parasitic pathogens has been reported in patients receiving glucocorticoid therapy (Table 108.1). The anti-inflammatory properties of the glucocorticoids also can modify typical signs and symptoms of infection, resulting in presentation at a later stage of the infection.[11]

TABLE 108.1

Infections Reported With Excess Risk or Severity in Patients Treated With Corticosteroids

Bacteria	Gram-positive—*Staphylococcus aureus, Listeria monocytogenes, Nocardia* spp. Gram-negative—*Pseudomonas, Klebsiella, Salmonella, Legionella* spp. *Mycobacterium* spp.
Fungi	*Aspergillus, Candida, Cryptococcus*, endemic mycoses, *Fusarium, Scedosporium, Trichosporon*, zygomycetes
Viruses	Herpesviruses, enteroviruses, hepatitis B and hepatitis C
Parasites	*Strongyloides stercoralis*

Bacterial Infections

Bacterial infections are the most common complication of corticosteroid use, and potentially any bacterial pathogen can be causative.[9] Bacterial sepsis occurred 1.5 times more frequently in adult and pediatric patients receiving systemic corticosteroids in one meta-analysis; among all patients in the dataset, the mean daily drug exposure was equivalent to 35 mg of prednisone, with the mean total exposure of 2200 mg.[12] A meta-analysis of prediction models for neonatal intensive care unit (NICU)–associated sepsis found postnatal corticosteroid use to have a statistically significant predictive association.[13] Other studies of NICU-associated sepsis have demonstrated increased rates associated with antenatal corticosteroids to promote pulmonary maturation as well as postnatal corticosteroids, primarily dexamethasone. These risks must be considered in context of demonstrated benefits of antenatal corticosteroids to reduce intraventricular hemorrhage, respiratory distress syndrome, bronchopulmonary dysplasia, and all-cause neonatal mortality.[14]

Surgical site infections are significantly increased among patients receiving long-term corticosteroid immunosuppressive therapy, including neonatal and pediatric patients younger than 5 years undergoing complex cardiac surgery,[15,16] and data suggest that corticosteroids may be associated with increased overall morbidity after cardiac surgery, particularly in lower risk patients.[17] An increased risk for surgical site infection has been associated with corticosteroid use in adults with ulcerative colitis.[18]

Long-term corticosteroid use increases the risk for bacterial opportunistic infections related to impaired cell-mediated immunity. Bacterial pathogens include mycobacteria and *Nocardia* and *Legionella* spp.[19,20] In a large case-control study of adults, the adjusted odds ratio of tuberculosis in the group receiving corticosteroids compared with no steroid use was 4.9 (95% CI, 2.9, 8.3).[21] Pediatric-specific data are limited.

Fungal Infections

Invasive fungal infections are most frequently observed in patients receiving chronic corticosteroid therapy who are profoundly immunocompromised, such as hematopoietic stem cell transplantation (HSCT) and solid organ transplantation patients, oncology patients, and patients with collagen-vascular disorders.[22] Higher doses and longer duration of glucocorticoid therapy are associated with higher risk and worse prognosis for invasive fungal infection, and lower doses and alternate-day regimens have been shown to be protective.[23,24] In addition to increasing risk for invasive fungal infection, the anti-inflammatory properties of glucocorticoids also can result in delayed recognition because of modified signs and symptoms of infection.[22] Invasive aspergillosis is an important pathogen in allogeneic bone marrow transplantation and is the most common cause of infectious death among these patients, resulting in 10% of mortality in the late posttransplantation period.[22-23] However, invasive aspergillosis, the most common mold infection associated with glucocorticoid administration, has been reported in patients receiving only high-potency inhaled glucocorticoids, without other immunosuppressive therapies.[25]

Glucocorticoids are an independent risk factor for invasive yeast infections, including invasive candidiasis and candidemia. Increased risk is reported in patients with cancer and HSCT, hemodialysis, systemic lupus erythematosus, or surgery and in premature neonates.[22,26–29] In one study of premature neonates, risk for invasive candidiasis was 7.5-fold higher in infants treated with glucocorticoids for hypotension compared with unexposed infants.[29] In a recent study during routine use of antifungal prophylaxis in premature infants, corticosteroid use was not a statistically significant risk factor for invasive candidiasis, suggesting that risk can be successfully mitigated.[30]

Pneumocystis jirovecii pneumonia (PCP) is associated with prolonged and high-dose glucocorticoid administration in children and adults with cancer, solid-organ and allogeneic bone marrow transplantations, and collagen-vascular disorders.[22] PCP also has occurred in asthmatic children treated with high doses of systemic corticosteroids.[20] Crypotococcal infections, including meningitis, have been described in non-AIDS patients receiving glucocorticoids, although no specific pediatric data are available.[22] Primary and reactivated endemic fungal infections also are reported in patients receiving long-term glucocorticoids. Although histoplasmosis is reported most frequently, coccidioidomycosis, blastomycosis, penicilliosis, and sporotrichosis also have been reported, primarily in adults.[22]

Viral Infections

Herpesviruses.

The most frequently described viral complication of corticosteroid use is reactivated herpesvirus infections. Oncology and transplantation patients with significant immunosuppression are at greatest risk. Severe fulminant hepatitis is associated with herpes simplex virus (HSV) or varicella-zoster virus (VZV), and cytomegalovirus (CMV) is an important cause of pneumonia in immunosuppressed patients with prominent T-lymphocyte dysfunction.[19] Pediatric data show mixed results regarding the risk for severe primary VZV infection in patients receiving corticosteroids. In a case-control population chosen to represent immunocompetent children exposed to corticosteroids, there was no increased risk for severe VZV (odds ratio [OR], 1.6; 95% CI, 0.2,16.9); conversely, in a case-control cohort inclusive of immunosuppressed patients receiving glucocorticoids, including children undergoing treatment for acute leukemia, the OR for severe varicella was a remarkable at 178 (95% CI, 59, 541).[31,32] Of note, both of these studies were conducted before the era of universal varicella immunization in the US. When primary VZV infection is diagnosed in children receiving 2 mg/kg/day of corticosteroids for >14 days, intravenous acyclovir therapy is recommended to reduce the risk for severe infection.[33]

Other Common Viruses.

The course of viral infections can be more severe when corticosteroids are given as therapeutics. A meta-analysis of data from the 2009 H1N1 influenza pandemic did not support the use of corticosteroids for severe influenza and showed a trend toward increased mortality among corticosteroid-treated patients of all ages.[34] In addition, during enterovirus 71 outbreaks, children receiving injectable glucocorticoids early in the illness as outpatients were more likely to progress to severe, life-threatening infection.[35]

Hepatitis B and C Viruses.

Reactivation to active replication of hepatitis B virus (HBV) and hepatitis C virus (HCV) can follow corticosteroid therapy with clinically significant consequences. In addition to the immunosuppressive effects, corticosteroids stimulate HBV replication in vitro. Although most clinical data are in adults receiving chemotherapy for malignancies, in a meta-analysis of risk factors among oncology patients, younger age and corticosteroid use were significant risks for HBV reactivation.[36–38]

Parasitic Infections.

Corticosteroid use increases the risk for symptomatic strongyloidiasis (RR, 2.29–3.3).[39] Severe strongyloidiasis due to amplification of the parasite's autoinfective cycle has been associated with glucocorticoids used for chemotherapy, after transplantation, and for rheumatologic conditions in adults. Disease can occur 30 years or later after infestation in endemic areas, and overall mortality is high (59%), with secondary bacterial or fungal sepsis significantly contributing to morbidity and mortality.[40]

Other Considerations

Administration of Vaccines

For patients receiving corticosteroid therapy lasting >2 weeks at doses ≥2 mg/kg/day of prednisone or its equivalent, or ≥20 mg/day for those weighing more than 10 kg, live virus vaccines should be deferred for 1 month after corticosteroid discontinuation. Prolonged corticosteroid therapy can reduce the immunologic responses to vaccines, including influenza and pneumococcal vaccines.[41,42] Inactivated vaccines can be given routinely while children are receiving corticosteroid therapy, or they can be deferred until therapy ends if the condition requiring corticosteroid treatment is anticipated to resolve and the patient can be recalled for vaccine administration.[33] When initiation of corticosteroid therapy can be anticipated, live virus vaccines should be given ≥4 weeks before, and inactivated vaccines ≥2 weeks before commencement of immune suppression with corticosteroids.[33]

Respiratory syncytial virus (RSV) prophylaxis with palivizumab may be indicated for certain patients requiring chronic corticosteroid use. The American Academy of Pediatrics recommends RSV seasonal palivizumab administration for former preterm infants born before 32 weeks, 0 days of estimated gestational age who required at least 28 days of oxygen after birth and who continue to require supplemental oxygen, chronic systemic corticosteroid therapy, or bronchodilator therapy within 6 months of the start of their first or second RSV season.[43]

Prevention of Opportunistic Infection

Patients initiating long-term corticosteroid therapy first should be screened with a tuberculin skin test or interferon γ release assay, and those identified with latent tuberculosis infection should be treated with an appropriate regimen.[44,45] Patients requiring prednisone doses of ≥20 mg/day for >30 days should also be considered for PCP prophylaxis using trimethoprim-sulfamethoxazole, dapsone, or atovaquone.[46] To prevent severe strongyloidiasis, oral ivermectin or albendazole is recommended for patients who have lived in or traveled to endemic areas even if the risk was years before initiation of immunosuppression with corticosteroids.[47]

Management of Patients Receiving Cortiocosteroid Therapy

Clinicians should maintain a low threshold for considering infection in patients receiving corticosteroids because classical signs and symptoms can be altered. Diagnostic and therapeutic considerations should include both typical and opportunistic infections. Decisions regarding whether corticosteroids should be continued in the presence of documented infection should be individualized, considering adverse infectious complications with continuation, the patient's underlying condition, and the potential for corticosteroid-related hypothalamic-pituitary-adrenal axis suppression and adrenal insufficiency with discontinuation.[48]

Future Directions

Future directions in the management of immunosuppressive agents and the conditions requiring them should include investigation into more specific targets for immunosuppression that minimize adverse effects and degree of immune impairment, along with improved diagnostics to identify infectious complications expeditiously in patients who may not manifest typical inflammatory signs and symptoms. Use of molecular diagnostics to identify respiratory virus should enlighten potential risks of corticosteroid use for status asthmaticus in acutely infected children.

Epidemiology and Prevention of HIV Infection in Children and Adolescents

Jennifer S. Read

The epidemiology of infection with human immunodeficiency virus type 1 (HIV) in children and adolescents has evolved dramatically since the first case of pediatric HIV infection was described in 1983.[1] This evolution is due in part to improvements in the management of HIV infection, with resultant increased survival of infected individuals. This chapter addresses the epidemiology of HIV infection among children and adolescents, clinical manifestations and progression of disease, and prevention of HIV infection in children and adolescents.

Epidemiology

The epidemiology of HIV infection varies dramatically between resource-poor and resource-rich settings around the world. Estimates of the extent of the HIV epidemic, globally and in the United States, are updated regularly by the Joint United Nations

Programme on HIV/AIDS (UNAIDS)[2] and by the US Centers for Disease Control and Prevention (CDC),[3] respectively. In the US, black and other minority infants, children, and adolescents are disproportionately affected by HIV infection.[3] HIV transmission to infants, children, and adolescents can occur through sexual contact (vaginal, anal, or orogenital), percutaneous blood exposure (from contaminated needles or other sharp instruments), mucous membrane exposure to contaminated blood or other body fluids, and transfusion with contaminated blood products.[4] Children also can acquire HIV infection through mother-to-child transmission.[4]

Of the estimated 36.7 million people living with HIV infection in 2015, 17.8 million were women and 1.8 million were children younger than 15 years, and most HIV-infected people (25.5 million) resided in sub-Saharan Africa.[2] An estimated 2.4 million HIV-infected individuals were in western and central Europe and North America. Of the estimated 2.1 million new infections in 2015 (91,000 in western and central Europe and North America), 1.9 million were among adults and 150,000 among children.[2] Finally, there were an estimated 1.1 million AIDS-related deaths in 2015 (22,000 in western and central Europe and North America).[2] In 2014, the number of persons living with a diagnosis of HIV infection in the US and dependent areas with confidential name-based HIV infection reporting included 2494 children (<13 years of age).[3]

Both in the US and globally, mother-to-child transmission is the most common means of acquisition of HIV infection by children (Table 109.1). For example, of the 2494 children reported to be living with HIV infection in the US in 2014,[3] 2012 (81%) were classified as having acquired infection through mother-to-child transmission.[3] Although there has been a dramatic decrease in the rate of mother-to-child transmission of HIV and in the number of pediatric HIV infections and AIDS cases in the US, mother-to-child transmission has not been eliminated in the US. In 2006, there were an estimated 171,400 HIV-infected women aged 13 to 44 years in the US and five dependent areas, with an estimated 8700 births to these women.[5] The estimated number of cases of mother-to-child transmission of HIV in the US peaked in 1991 (1650 cases).[6] By 2005, the number of cases of mother-to-child transmission in the US had decreased to an estimated 215 to 370, representing a transmission rate of approximately 2.8%.[7]

TABLE 109.1

Modes of Acquisition of HIV Infection in Children and Adolescents

Children	Adolescents
MOST COMMON	
Mother-to-child transmission	Sexual transmission • Males: male-to-male sexual transmission • Females: heterosexual transmission • Injection drug use
OTHER	
Transfusion of contaminated blood or blood products if effective screening not available (e.g., among patients with hemophilia early in the HIV epidemic in the US) Mucous membrane exposure to contaminated blood or other body fluids (e.g., through receipt of food that has been prechewed by an HIV-infected caregiver with bleeding gums or open sores in the mouth) Sexual abuse	Percutaneous blood exposure (from contaminated needles or other sharp instruments, e.g., with tattooing)

Mother-to-child transmission of HIV can occur during pregnancy, around the time of labor and delivery, and postnatally (through breastfeeding).[8] Most transmission occurs during the intrapartum period (both in breastfeeding and nonbreastfeeding populations).[9] Rates of mother-to-child transmission of HIV were calculated in studies conducted in various countries before the development and implementation of interventions to decrease transmission.[10] Usually a transmission rate in the range of 25% to 30% was reported. Higher transmission rates were observed in resource-poor settings (13%–42%) compared with rates in resource-rich settings (14%–25%), in part attributed to the greater proportion of breastfeeding women in resource-poor settings.

Various risk factors for mother-to-child transmission of HIV have been identified or are under investigation and can be categorized as follows: (1) the amount of virus to which the child is exposed (e.g., maternal viral load,[11–15] expressed as copies/mL of HIV RNA); (2) the duration of such exposure (e.g., the duration of ruptured membranes[16] or of breastfeeding,[17] vaginal versus cesarean delivery before labor and before ruptured membranes[18,19]); and (3) other factors, including those facilitating the transfer of virus from mother to child (e.g., mixed breastfeeding,[20,21] maternal breast pathology,[13,22–24] and infant oral candidiasis[23,24]). In addition to these risk factors, characteristics of the virus and the child's susceptibility to infection are important.

Improved estimation of HIV incidence is now possible with newer assays that differentiate between recent and chronic HIV infections.[25] Many cases of HIV infection in young adults represent infections that actually were acquired during adolescence, but were not recognized until several years later. In 2014, the number of persons living with a diagnosis of HIV infection in US and dependent areas with confidential name-based HIV infection reporting included 6161 adolescents (13–19 years of age) and 32,195 young adults (20–24 years of age).[3] Among the estimated 734,506 male adults and adolescents living with HIV infection in 2014, 513,045 (70%) of these infections were acquired through male-to-male sexual contact, 83,020 (11%) were due to injection drug use, 53,166 (7%) were due to male-to-male sexual contact and injection drug use, and 77,479 (10%) were due to heterosexual contact[3] (see Table 109.1). In contrast, among the estimated 235,613 female adults and adolescents living with HIV infection in 2014, 175,581 (74%) were acquired through heterosexual contact and 53,222 (23%) from injection drug use[3] (see Table 109.1).

Aside from mother-to-child transmission, sexual transmission, and transmission related to intravenous drug use, other means of acquisition of HIV infection include transfusion of contaminated blood or blood products in settings in which routine and effective screening of blood is not available, percutaneous blood exposure (from contaminated needles or other sharp instruments), and mucous membrane exposure to contaminated blood or other body fluids (see Table 109.1).[4] The first case of pediatric HIV infection in the US was an infant who acquired HIV infection through a transfusion of contaminated blood.[1] Thousands of patients with hemophilia and other recipients of contaminated blood and blood products acquired HIV infection before screening of blood and blood products for HIV. Now, in the US and many other countries, blood, blood components, and clotting factors undergo effective screening procedures. As a result, transmission of HIV through transfusion of blood or blood products in the US has decreased substantially.[26–29] The risk for transmission of HIV through blood transfusions in the US in 2010 was estimated at 1 per 1,467,000.[29] In addition to intravenous drug use, other exposure to contaminated needles (e.g., with tattooing)[30] can result in HIV transmission. Possible transmission of HIV through receipt of food that has been prechewed by an HIV-infected caregiver with bleeding gums or open sores in the mouth has been reported.[31,32] There have been rare cases of household transmission of HIV between siblings,[33] but in these cases, there were opportunities for skin or mucous membrane exposure to HIV-infected blood. Thus all caregivers of HIV-infected children should receive education regarding universal precautions.[34,35] Transmission of HIV has not been described as a result of routine outpatient or inpatient care or in schools or childcare settings in the US.[4,36–38] Cases of HIV transmission to children through sexual abuse have been reported.[39–41]

Clinical Manifestations and Progression

Infection with HIV can result in a myriad of clinical manifestations. Acquired immunodeficiency syndrome, or AIDS, refers to the most advanced disease stage of HIV infection. AIDS is defined by the development of life-threatening manifestations, including opportunistic infections and neoplasms, due to progressive immunosuppression induced by HIV infection.

Previously, the CDC had classified HIV-infected children (below 13 years of age) according to their clinical status (ranging from N [not symptomatic], through A and B, to C [severely symptomatic; AIDS]) and immunologic status (category 1 [$CD4^+$ T-lymphocyte count or percentage indicating no evidence of immune suppression] to category 3 [severe suppression]).[42] Thus, combining both the clinical and immunologic staging of children resulted in categories of N1 through C3. This classification system took into account the age-related changes (<1 year, 1–5 years, 6–12 years) in the normal ranges of $CD4^+$ lymphocyte counts. The classification system for adolescents and adults similarly classified HIV-infected individuals according to their clinical and immunologic status, except that the clinical staging ranged from A to C (no category N).[43] In 2014, the CDC revised the surveillance case definition for HIV infection.[44] According to this new case definition, a confirmed case of HIV infection (whether in children [<13 years of age] or in adolescents and adults) can be classified into one of five HIV infection stages (stages 0, 1, 2, 3, or unknown).[44] Early infection is classified as stage 0, and AIDS is classified as stage 3.[44]

The natural history of HIV infection in infants who acquired HIV infection through mother-to-child transmission differs from that in adults. Plasma viral loads among untreated, infected infants increase rapidly after birth,[45] peaking at 1 to 2 months of age (median values of 318,000 and 256,000 copies/mL, respectively).[45] Untreated, viral loads decline slowly during the first 2 years of life,[46] reaching values observed in HIV-infected adults only at approximately 5 years of age.[47]

Studies of HIV-infected infants who acquired infection through mother-to-child transmission[48,49] that were published in the late 1990s, at a time when pediatric antiretroviral treatment was limited, described rapid progression of disease. For example, in a study of 128 HIV-infected children in North America,[48] the median ages of progression to clinical classes A, B, and C were 5, 11, and 48 months, respectively. In another study of 392 HIV-infected children in Europe, about 20% progressed to class C disease or death during the first year of life, and approximately 5% progressed per year thereafter.[49] The mortality rate at 6 years was 26%.[49] Early onset of clinical manifestations of HIV infection (lymphadenopathy, hepatomegaly, splenomegaly at 3 months of age or earlier) and positive HIV diagnostic testing within the first week of life were associated with more rapid disease progression.[48] In subsequent studies of HIV-infected children in Africa, more than one third of untreated, HIV-infected infants died by 12 months of age,[50] and approximately one half died by 24 months of age.[51]

After the introduction of more effective antiretroviral regimens, the morbidity and mortality associated with HIV infection among infants, children, adolescents, and adults has decreased substantially.[52–64] Opportunistic and other infections were uncommon among HIV-infected children in 2000 to 2004,[65] and infection rates were lower than those reported in earlier years.[66] Similarly, the incidence of certain noninfectious conditions (encephalopathy, pancreatitis, cardiac disorders) decreased between 2001 and 2006 among HIV-infected children and adolescents.[67]

In a randomized clinical trial conducted in South Africa, infants with early time-limited antiretroviral therapy had better clinical and immunologic outcomes than infants with deferred therapy.

Also, infants with early antiretroviral therapy did not have excess disease progression during subsequent treatment interruption.[68,69] Based on these data and the high risk for rapid progression of HIV infection in infants, urgent antiretroviral therapy for all HIV-infected infants is recommended, regardless of clinical, immunologic ($CD4^+$ lymphocyte percentage), or viral load status.[70] For children aged 1 to <6 years, urgent treatment is recommended for those with CDC stage 3-defining opportunistic infections or stage 3 immunodeficiency ($CD4^+$ cell count <500 cells/mm^3).[70] Antiretroviral treatment is recommended for children aged 1 to <6 years with moderate HIV-related symptoms, those with a $CD4^+$ cell count of 500 to 999 cells/mm^3, and those who are asymptomatic or mildly symptomatic and who have a CD4 cell count ≥1000 cells/mm^3.[70] For children ≥6 years of age, urgent antiretroviral treatment is recommended for those with CDC stage 3-defining opportunistic infections or stage 3 immunodeficiency ($CD4^+$ cell count <200 cells/mm^3).[70] Antiretroviral treatment is recommended for children ≥6 years of age with moderate HIV-related symptoms, those with a $CD4^+$ cell count of 200 to 499 cells/mm^3, and those who are asymptomatic or mildly symptomatic and with a CD4 cell count ≥500 cells/mm^3.[70]

There is substantial variation in HIV disease progression among adolescents and adults; some individuals progress to AIDS in less than 5 years,[71] but some untreated individuals (so-called long-term nonprogressors) do not deteriorate clinically or immunologically for many years.[72,73] Current guidelines for initiation of antiretroviral therapy in HIV-infected adolescents and adults[74] recommend the initiation of antiretroviral therapy in all HIV-infected individuals, regardless of $CD4^+$ count, to decrease morbidity and mortality related to HIV infection. Antiretroviral therapy should be initiated as soon as possible after diagnosis of HIV infection, although in certain circumstances (i.e., related to clinical and/or psychosocial factors), therapy may be deferred.[74]

Prevention

Mother-to-child transmission represents the means by which virtually all infants and young children acquire HIV infection. Most adults and adolescents acquire HIV infection through sexual transmission or percutaneous exposure (e.g., intravenous drug use). Discussion of prevention of HIV transmission to children and adolescents focuses on these routes of transmission.

Prevention of Mother-to-Child Transmission

Prevention of mother-to-child transmission of HIV is just one component of the overall management of HIV-infected women and their children (Box 109.1). The World Health Organization (WHO) Strategic Approach to Prevention of Pediatric HIV Infection[75] includes four components: primary prevention of HIV infection; prevention of unintended pregnancies among HIV-infected women; prevention of transmission of HIV infection from mothers to children; and provision of ongoing support, care, and treatment to HIV-infected women and their families. Ideally, primary prevention of HIV infection occurs (e.g., an HIV-uninfected woman does not acquire HIV infection either before or during pregnancy). To facilitate prevention of acquisition of HIV infection, individuals should know their own and their sexual partners' HIV infection status. This is accomplished through provision of and access to HIV counseling and testing. Prevention of unintended pregnancies is crucial for women who acquire HIV infection. Antiretroviral therapy for HIV-infected women, for their own health and for prevention of mother-to-child transmission of HIV, as well as other interventions to prevent mother-to-child transmission, should be available. Finally, HIV-infected women and their children need ongoing support, care, and treatment, including infant feeding counseling and support.

Box 109.1

Prevention of Mother-to-Child Transmission of HIV

Antiretroviral agent(s)

- For the mother (for treatment of the mother's own HIV infection, for prevention of mother-to-child transmission of HIV)

- For the nonbreastfeeding infant (early postnatal period)

Cesarean delivery before labor and before rupture of membranes

Interventions to prevent breast milk transmission of HIV

- Complete avoidance of breastfeeding
- Exclusive breastfeeding when complete avoidance of breastfeeding is not feasible or safe
- Antiretroviral prophylaxis for the breastfeeding infant

Although different interventions to prevent mother-to-child transmission of HIV have been and are being investigated, efficacy has been demonstrated to date for only the following: antiretroviral use during pregnancy by HIV-infected women,[76–83] cesarean delivery before labor and before ruptured membranes,[18] complete avoidance of breastfeeding,[84] and (in settings where complete avoidance of breastfeeding is not feasible) exclusive breastfeeding,[85] antiretroviral prophylaxis administered to the infant while breastfeeding,[86–89] and antiretroviral use by breastfeeding mothers.[88,90]

Antiretroviral Agents

Maternal use of antiretroviral agents during the antepartum and intrapartum periods, and during the postpartum period if breastfeeding, as well as infant antiretroviral prophylaxis while breastfeeding, are associated with significant reduction in the rates of mother-to-child transmission of HIV. In the first efficacy trial of antiretroviral prophylaxis, zidovudine alone was given to mothers during pregnancy and the intrapartum period and to their infants.[76] Subsequently, the US Public Health Service issued guidelines regarding the use of zidovudine prophylaxis,[91] and such prophylaxis played a central role in the prevention of mother-to-child transmission in the US[92] and other resource-rich settings. More recently, an increasing number of HIV-infected women have been using combination antiretroviral therapy (cART) during pregnancy.[93] In 2015, results from a randomized trial demonstrated lower rates of mother-to-child transmission with cART regimens including three drugs (zidovudine, lamivudine, and lopinavir/ritonavir [0.5%] or tenofovir, emtricitabine, and lopinavir/ritonavir [0.6%]) compared with zidovudine, with a single dose of nevirapine at delivery, plus tenofovir and emtricitabine (1.8%).[83]

Antiretroviral agents prevent mother-to-child transmission of HIV by decreasing the viral load in maternal blood and genital secretions,[12,94] an important risk factor for vertical transmission.[94–96] In addition to decreasing viral load, other mechanisms of action of antiretroviral therapy in reducing vertical transmission are suggested by several observations. First, there is no threshold maternal plasma viral load below which transmission does not occur; transmission has been observed at all levels of maternal viral load.[94,96,97] Second, among women with lower plasma viral loads (<1000 copies/mL), more intensive maternal antiretroviral regimens are associated with lower risks for transmission.[98] Also, maternal plasma load at delivery and antepartum antiretroviral use are each independent risk factors for transmission.[93] Pre-exposure infant prophylaxis can be accomplished through the maternal use of antiretroviral agents that cross the placenta and result in adequate systemic drug concentrations in the infant. Postexposure infant prophylaxis can be achieved through administration of antiretroviral agents to the infant after birth. In this situation, the antiretroviral agents can protect the infant from acquiring infection through maternal microtransfusions of blood during labor or from virus swallowed by the infant during delivery. The efficacy and effectiveness of intrapartum or neonatal antiretroviral regimens for prevention of mother-to-child transmission (i.e., initiated too late to prevent transmission by decreasing maternal viral load)[81,99–104] lend further support to the benefit of infant pre-exposure and postexposure prophylaxis.

Guidelines addressing the use of antiretroviral therapy during pregnancy have been developed by the US Department of Health and Human Services (DHHS) Panel on Treatment of HIV-Infected

Pregnant Women and Prevention of Perinatal Transmission,[105] the WHO,[107] and other groups. Guidelines for the use of antiretroviral agents in HIV-infected pregnant women in the US have evolved over the years.[105] Current recommendations are for all pregnant, HIV-infected women to use cART to prevent mother-to-child transmission of the virus, irrespective of the woman's plasma $CD4^+$ count or viral load (copies/mL), and such therapy should be initiated as early in pregnancy as possible.[105] In general, indications for initiation of antiretroviral therapy in women of reproductive age, pregnant women, or postpartum women are the same as those for other HIV-infected adults and adolescents.[74] British guidelines for the management of HIV-infected women include zidovudine alone as a valid option for women with higher $CD4^+$ counts and lower pretreatment plasma viral loads (<10,000 copies/mL) who do not want to use cART during pregnancy and who are willing to give birth by planned cesarean delivery.[108]

Antiretroviral resistance testing should be performed in all HIV-infected, antiretroviral-naïve pregnant women before initiation of antiretroviral treatment (if the pretreatment viral load is above the threshold for resistance testing [i.e., >500−1000 copies/mL]).[105] For women with viral loads above the threshold for resistance testing while using antiretroviral agents and for those who have suboptimal viral suppression after initiating antiretroviral therapy during pregnancy, resistance testing should be performed before modifying antiretroviral regimens.[105] Of note, for women who come to attention late in pregnancy, empiric antiretroviral therapy should be initiated without waiting for resistance testing results. After results become available, the antiretroviral regimen can be modified if necessary.[105]

Women using cART during pregnancy should continue this regimen as much as possible around the time of delivery, and intrapartum (intravenous) zidovudine is not required for women with good adherence to cART who have viral loads ≤1000 copies/mL.[105] However, intravenous zidovudine should be administered to other HIV-infected women, especially those with a viral load of >1000 copies/mL or an unknown viral load near delivery.[105] For women of unknown HIV infection status who present in labor, expedited antigen/antibody testing should be performed. If this testing is positive, maternal intravenous zidovudine and infant cART should be initiated immediately, without waiting for the results of an HIV-1/HIV-2 antibody differentiation assay.[105]

All newborn infants of HIV-infected women should receive antiretroviral postexposure prophylaxis, irrespective of whether the mother used antiretroviral agents during pregnancy.[105] A 4-week regimen of zidovudine is recommended for transmission prophylaxis for full-term infants whose mothers adhered to a cART regimen during pregnancy (with sustained viral suppression).[105] A longer (6-week) regimen of antiretroviral prophylaxis (with a combination ARV regimen) is recommended for all high-risk infants (i.e., those whose mothers did not use antepartum or intrapartum ARVs or whose mothers used only intrapartum ARVs, and those whose mothers used cART but without sustained viral suppression).[105] In the United Kingdom, a 4-week infant antiretroviral prophylaxis regimen is recommended.[108] Antiretroviral prophylaxis for infants should begin as soon as possible (preferably within 6–12 hours) after birth.[105] Clinical trials are planned to address the question of whether using cART for HIV-exposed, high-risk infants will affect the establishment and persistence of HIV infection, as well as to assess the safety of such an approach.

The effectiveness of antiretroviral therapy in improving maternal $CD4^+$ lymphocyte counts and decreasing plasma viral load should be monitored carefully in any HIV-treated patient population, including infected pregnant women.[105] Laboratory monitoring to assess antiretroviral drug-related toxicities is based on the known adverse events related to the drugs being used.[105]

In addition, the benefits of antiretroviral agents for HIV-infected women and their infants (treatment of the mother's own HIV infection, prevention of mother-to-child transmission of HIV) must be weighed against adverse events associated with these drugs. Potential adverse events related to in utero exposure to antiretroviral agents include congenital anomalies, malignancies, mitochondrial toxicity, and preterm birth.

Studies evaluating in utero exposure to antiretroviral agents, especially first-trimester exposure, generally have not demonstrated significant associations between exposure and infant congenital anomalies.[111–116] Some studies[116,117] have reported a higher risk for congenital anomalies among infants with first-trimester exposure to efavirenz, but more research regarding first-trimester exposure to the drug is necessary to evaluate potential risks more conclusively. However, because of potential central nervous system abnormalities with first-trimester exposure to efavirenz and similar findings in primates, the use of efavirenz during the first trimester of pregnancy should be avoided.[105]

Findings to date regarding the short-term (e.g., within the first 2–4 years of life) risk for malignancies among infants with in utero antiretroviral exposure are reassuring.[118–121] Nonetheless, the possibility that children with in utero exposure are at increased risk for cancer at older ages remains. Children with exposure to antiretroviral agents should have follow-up into adulthood because of the potential for carcinogenicity of antiretroviral agents.[105]

In utero exposure to nucleoside and nucleotide analogue reverse transcriptase inhibitors has been linked to mitochondrial dysfunction in French infants.[122,123] However, results of other studies from the US and Europe[124–129] have not corroborated these results. Further research in this area is needed. Even if a clear association between in utero antiretroviral exposure and mitochondrial dysfunction is delineated, the absolute risk for severe mitochondrial dysfunction appears to be low and outweighed by the benefit of antiretroviral agents in reducing the risk for mother-to-child transmission of HIV.

The possibility of an association between use of cART, especially those regimens containing protease inhibitors, during pregnancy and infant preterm birth should be considered, although currently available data are conflicting.[130–150] In general, however, the benefits of antiretroviral use during pregnancy are considered to outweigh the small possible risk for preterm birth.

Neonatal anemia has been associated with in utero or early postnatal exposure to antiretroviral agents; therefore treated babies should have routine hematologic evaluation. Based on studies suggesting other laboratory abnormalities among infants with in utero or early postnatal exposure to antiretroviral agents,[151–157] some experts recommend more extensive laboratory assessments, such as a complete blood count with differential of white cells and hepatic transaminase assays.

WHO guidelines regarding the use of antiretroviral agents[107] recommend initiation in all HIV-infected pregnant or breastfeeding women regardless of WHO clinical stage or $CD4^+$ count and continuation lifelong. All infants born to HIV-infected mothers should receive antiretroviral prophylaxis. For infants of women who are using ART and are breastfeeding, 6 weeks of infant prophylaxis with daily nevirapine is recommended.[107] For infants receiving replacement feeding, 4 to 6 weeks of infant prophylaxis is recommended (with daily nevirapine or twice-daily zidovudine).[107] High-risk infants (infants who are at high risk of acquiring HIV infection because they are [1] born to mothers with chronic HIV infection who received less than 4 weeks of antiretroviral therapy by the time of delivery; [2] born to mothers with chronic HIV infection and a viral load above 1000 copies/mL in the 4 weeks prior to delivery; [3] born to mothers with acute HIV infection during pregnancy or during breastfeeding; or [4] born to mothers identified for the first time as HIV-infected during the postpartum period) should receive prophylaxis with twice-daily zidovudine and once-daily nevirapine for the first 6 weeks of life (irrespective of whether breastfed or formula fed).[107] Such breastfed infants should continue prophylaxis for an additional 6 weeks (for a total of 12 weeks of infant prophylaxis).[107] The WHO guidelines recommend initiation of antiretroviral therapy in all HIV-infected children younger than 10 years of age, regardless of WHO clinical stage or $CD4^+$ cell count.

Cesarean Delivery Before Labor and Before Ruptured Membranes

In the late 1990s, results from both a multicenter, randomized clinical trial conducted in Europe and a meta-analysis of prospective cohort studies conducted in North America and Europe demonstrated the effectiveness of cesarean delivery before labor and before ruptured membranes in reducing mother-to-child transmission of HIV.[18,19] In the clinical trial, the risk for mother-to-child transmission of HIV was 80% lower among women allocated to the group who underwent cesarean delivery before labor and before rupture of membranes; the risk for transmission was highest among women who delivered vaginally (10.2%), followed by those who had a cesarean delivery after onset of labor or ruptured membranes (8.8%), with the lowest risk among those who underwent cesarean delivery before labor and before rupture of membranes (2.4%).[18] The individual patient meta-analysis of data from 15 prospective cohort studies found that, after controlling for maternal age, use of antiretroviral agents during pregnancy (mostly zidovudine alone), and infant birth weight, cesarean delivery before labor and before ruptured membranes was associated with a lower risk for transmission of HIV (adjusted odds ratio [OR], 0.43; 95% confidence interval [CI], 0.33–0.56) compared with other modes of delivery.[19]

A large proportion of mother-to-child transmission of HIV occurs during the intrapartum period.[8,9] One potential mechanism of intrapartum HIV transmission is fetal exposure to infected maternal blood and cervicovaginal secretions. An early study of twins born to HIV-infected women found that the first-born twin was at higher risk for HIV transmission compared with the second twin,[158] suggesting that time spent with exposure to infected blood and secretions in the vagina increased risk. In addition, a longer duration of ruptured membranes is associated with a greater risk for mother-to-child transmission of HIV.[159] For each hour increase in the duration of ruptured membranes, there is an approximate 2% increase in the risk for mother-to-child transmission of HIV.[158] This association suggests that intrapartum transmission results from ascending infection from the lower genital tract, after the integrity of the amniotic membranes is disrupted. Another potential mechanism for mother-to-child transmission of HIV is microtransfusions of maternal blood during uterine contractions. Placental microtransfusions occur when a small amount of maternal blood crosses the placenta to the fetus. Two studies assessing the levels of placental alkaline phosphatase found that the lowest cord placental alkaline phosphatase levels, and thus the lowest volumes of maternal-fetal transfusion, were among those undergoing cesarean delivery before labor and before rupture of membranes.[160,161]

Based on these studies, the American College of Obstetricians and Gynecologists (ACOG) recommended that: (1) HIV-infected women with plasma viral loads >1000 copies/mL should be counseled on the benefits of cesarean delivery before labor and before rupture of membranes to prevent mother-to-child transmission; (2) cesarean delivery should be performed at 38 completed gestational weeks, based on the best clinical estimate, to minimize the odds for onset of labor and rupture of the membranes; (3) HIV-infected women should receive antiretroviral agents during pregnancy and without interruption before the cesarean delivery; and (4) women should receive intravenous zidovudine 3 hours before the cesarean delivery, before labor and before rupture of membranes.[161] After the release of data regarding mode of delivery and mother-to-child transmission of HIV,[18,19] cesarean delivery for HIV-infected women was performed with increasing frequency in clinical centers in the US.[163] However, HIV-preventive cesarean delivery generally is not feasible in resource-poor settings because of the lack of a skilled attendant during labor and for other reasons. Scheduled cesarean delivery at 38 weeks' gestation is recommended for HIV-infected women in the US with plasma viral loads above 1000 copies/mL or unknown plasma viral loads near the time of delivery, irrespective of use of antepartum antiretroviral agents.[105]

Because cesarean delivery is a major operative procedure, there are concerns about potential risks to the mothers and infants. Compared with vaginal delivery among HIV-uninfected women, cesarean delivery is associated with increased risk for intraoperative and postoperative complications, particularly after emergency cesarean delivery.[164–167] Several studies have compared postpartum morbidity according to mode of delivery among HIV-infected women.[18,168–171] The results of these studies, summarized in a Cochrane review,[172] indicate that the risk for postpartum morbidity, primarily infectious (i.e., urinary tract infection, pneumonia, wound infection, septicemia, and episiotomy infection), was highest with nonelective cesarean delivery, intermediate with elective cesarean delivery, and lowest with vaginal delivery. The DHHS Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission[105] has concluded that the observed postpartum morbidity associated with cesarean delivery before labor and before ruptured membranes among HIV-infected women is not of sufficient frequency or severity to outweigh the benefit of decreased transmission of HIV to the infant.

Studies among HIV-uninfected women have demonstrated that infants who are delivered before 39 weeks' gestation are at an increased risk for neonatal respiratory morbidity and other complications. In two recent analyses of data from prospective cohort studies,[173,174] respiratory morbidity among neonates of HIV-infected pregnant women was assessed according to mode of delivery. In an analysis of more than 1000 mother-infant pairs in North America, the authors concluded that there was minimal neonatal respiratory morbidity risk in near-term infants born by cesarean delivery before labor and rupture of membranes.[173] In an analysis of more than 1400 HIV-infected women and their infants in Latin America, few children born by cesarean delivery before labor and before ruptured membranes for prevention of mother-to-child transmission of HIV had respiratory distress syndrome or transient tachypnea of the newborn, and only a minority required ventilator support.[174] It therefore appears that the benefits of cesarean delivery for prevention of mother-to-child transmission of HIV outweigh the small risk for respiratory morbidity among near-term infants.[173,174]

To strike a balance between minimizing the risks for iatrogenic prematurity and ensuring that the cesarean delivery before labor and before rupture of membranes is performed before the onset of labor, the ACOG recommends that infants of HIV-infected women should be delivered a week earlier (at 38 completed weeks of gestation) than is customary among uninfected women (39 completed weeks of gestation).[162] Although the ACOG generally recommends testing amniotic fluid if elective delivery is being considered before 39 week to determine fetal pulmonary maturity,[175] amniocentesis should not be performed routinely in HIV-infected women. Therefore clinicians should depend on the best clinical estimate of gestational age to determine when to deliver.[176]

Unresolved questions regarding mode of delivery and prevention of mother-to-child transmission of HIV include whether cesarean delivery before labor and before ruptured membranes is beneficial among HIV-infected, pregnant women with low plasma viral loads (<1000 copies/mL) and whether there is a benefit of cesarean delivery before labor and before rupture of membranes among women who are using cART. In one recent study, the mother-to-child transmission rate in term births (including all modes of delivery) according to maternal viral load at delivery was 0.6% (<400 copies/mL).[177] A similarly low rate of transmission (0.8%) has been observed among women using cART for at least the last 14 days of pregnancy, regardless of mode of delivery.[178] However, analyses of data from the European Collaborative Study[179] demonstrated an 80% lower risk for transmission with cesarean delivery before labor and before rupture of membranes when adjusting for use of cART and preterm birth (adjusted OR, 0.20; 95% CI, 0.05–0.65). Similarly, among 560 women with undetectable viral loads, cesarean delivery before labor and before rupture of membranes was associated with a 90% lower risk for transmission (OR, 0.10; 95% CI, 0.03–0.33).[180] More recent data from the UK and Ireland regarding HIV-infected women with plasma viral loads of 50 to 399 copies/mL suggest the risk for mother-to-child transmission among women with a scheduled cesarean delivery is less than one half that in women intending to delivery vaginally.[181]

Interventions to Prevent Breast Milk Transmission of HIV

Both the CDC[182] and the American Academy of Pediatrics (AAP)[183,184] recommend that HIV-infected women in the US not breastfeed their children. These recommendations are based in large part on the results of a randomized clinical trial conducted in Kenya, where the observed rate of mother-to-child transmission of HIV among mothers randomized to not breastfeed was significantly lower than among mothers randomized to breastfeed (20.5% vs. 36.7% at 2 years, $P < 0.001$).[84]

The evidence for breast milk transmission of HIV and risk factors for such transmission have been summarized[185]; these include longer duration of breastfeeding, more advanced HIV disease in the mother, the child's susceptibility to infection, and factors that may facilitate transfer of HIV from mother to child or are otherwise associated with an increased risk for breast milk transmission. A meta-analysis incorporating data from thousands of breastfeeding children of HIV-infected women in sub-Saharan Africa[17] demonstrated that breast milk transmission of HIV contributes substantially to overall mother-to-child transmission. The longer breastfeeding continues, the greater the cumulative risk for HIV transmission. More advanced maternal disease stage, as manifested by lower $CD4^+$ lymphocyte counts, is a risk factor for breast milk transmission of HIV,[13,24] along with higher maternal peripheral blood or human milk viral load.[13–15] Factors that facilitate the transfer of the virus from mother to child and other factors, including maternal breast abnormalities, infant candidiasis, and mixed feeding, are associated with breast milk transmission of HIV.[13–15,20,22–24]

If complete avoidance of breastfeeding is not safe or feasible, specific interventions to prevent breast milk transmission of HIV can be implemented. Some of these interventions have been evaluated in clinical trials, whereas others are currently under study.

Because a longer duration of breastfeeding is associated with a greater risk for transmission,[17,84] early weaning was thought to be a reasonable intervention to decrease the risk for transmission. However, the morbidity associated with complete avoidance of breastfeeding and with early weaning, owing to contaminated water used in the preparation of replacement feeds, serves to counterbalance the benefits of such interventions to prevent mother-to-child transmission of HIV. For example, in the clinical trial of formula feeding versus breastfeeding, the two groups of children experienced similar mortality and malnutrition rates during the first 2 years of life.[186] Similarly, studies in Malawi and Uganda documented increased risks for severe gastroenteritis[187,188] and gastroenteritis-associated mortality[187] among HIV-exposed infants. In a randomized trial evaluating the safety and efficacy of early weaning,[189] there was no statistically significant difference in HIV-free survival between those children who ceased breastfeeding at about 4 months of age and those who continued breastfeeding ($P = 0.27$).

Because more advanced maternal disease (e.g., as manifested by a higher maternal viral load in breast milk) is associated with a greater risk for mother-to-child transmission of HIV, two types of interventions have been proposed to decrease the infectiousness of the breast milk of HIV-infected mothers: maternal use of antiretroviral agents while breastfeeding, and treatment (chemical or heat) of breast milk. Two randomized clinical trials conducted in sub-Saharan Africa evaluated the use of antiretroviral prophylaxis by breastfeeding women in the reduction of mother-to-child transmission of HIV.[88,90] In the BAN trial, HIV-infected, breastfeeding mothers with a $CD4^+$ lymphocyte count of ≥250 cells/mm^3 and their infants were randomized at 1 week after delivery to receive maternal antiretroviral regimen for 28 weeks, infant nevirapine for 28 weeks, or no prophylaxis beyond the first week of age. Before randomization, all mothers and infants had received standard perinatal prophylaxis, which included a single dose of oral nevirapine given to mothers in labor and to their infants immediately after birth. In addition, all mothers had received zidovudine and lamivudine as a single tablet every 12 hours from the onset of labor to 7 days after birth, and all infants received zidovudine until 7 days of age. Of 2369 mother-infant pairs who were randomized, 5% of infants were HIV-infected at 2 weeks of life. The estimated risk for mother-to-child transmission of HIV between 2 and 28 weeks was higher in the control group (5.7%) than in the other groups (maternal regimen group: 2.9%, $P = 0.009$; infant regimen group: 1.7%, $P < 0.001$). The estimated risks for infant HIV infection or death between 2 and 28 weeks were 7% in the control group, 4.1% in the maternal regimen group ($P = 0.02$), and 2.6% in the infant regimen group ($P < 0.001$).[88] In the Kesho Bora study, women with $CD4^+$ lymphocyte counts between 200 and 500 cells/mm^3 were randomized to either (1) zidovudine with lamivudine and lopinavir/ritonavir (triple-ARV) at 28 to 36 weeks' gestation until 6 months postpartum; or (2) zidovudine at 28 to 36 weeks' gestation until the onset of labor, and then zidovudine with lamivudine and one dose of nevirapine at the onset of labor, followed by (in a later version of the protocol) zidovudine with lamivudine until 1 week after delivery (ZDV/sdNVP). All infants received one dose of nevirapine within 72 hours of birth along with 1 week of zidovudine. Among 882 enrolled women, 824 were randomized and delivered 805 singleton or first, live-born infants. The cumulative risk for HIV transmission at 12 months was 5.4% in the triple-ARV arm and 9.5% in the ZDV/sdNVP arm ($P = 0.03$), a 43% risk reduction.[90] Heat and chemical (e.g., sodium dodecyl sulfate) treatments of breast milk to decrease the amount of cell-free and cell-associated HIV have been evaluated in several studies.[190,191] In addition, a method of “flash heating” of breast milk[102] may be evaluated further in East Africa.

Because various factors facilitate the transfer of the virus from mother to child or are otherwise associated with a greater risk for mother-to-child transmission (e.g., maternal breast abnormalities, infant candidiasis, mixed breastfeeding), interventions to prevent or treat such factors have been developed. For example, programs have been developed to educate HIV-infected women who choose to breastfeed, addressing proper positioning during breastfeeding, promptly seeking medical care if breast abnormalities develop or if the infant develops oral candidiasis or other lesions, and avoiding breastfeeding from a breast with mastitis or other abnormalities. Studies conducted in Brazil and South Africa suggest a lower risk for transmission with exclusive breastfeeding compared with mixed breastfeeding.[20,193] Additional studies in Zimbabwe,[21] South Africa,[85] and Zambia[189] support the association of exclusive breastfeeding with a lower risk for mother-to-child transmission of HIV. For example, the transmission rate among infants who were still exclusively breastfeeding at 6 months of age was 15%, but the rate was higher among those with mixed feeding at 6 months of age (27% among those who initiated mixed feeding before 14 weeks and 26% for those who initiated mixed breastfeeding after 14 weeks).[85] It is noteworthy that although mixed feeding has been hypothesized to damage the intestinal mucosa, thus facilitating HIV infection of the infant through increased permeability or intestinal immune activation, the evidence to date do not support this hypothesis.[194] The exact mechanism by which mixed feeding is associated with a higher risk for transmission of HIV remains controversial.

Finally, interventions to decrease infant susceptibility to infection while breastfeeding (e.g., active and passive immunization of the infant, administration of antiretroviral prophylaxis to the infant while breastfeeding) have been or are being evaluated. Studies of the safety and immunogenicity of active immunization for prevention of mother-to-child transmission of HIV have been initiated.[195,196] Similarly, passive immunization with polyclonal immune globulin has been evaluated in clinical trials in the US (formula-fed infants) and Uganda (predominantly breastfed infants).[195,196]

Several major studies have evaluated the efficacy of extended administration of antiretroviral prophylaxis to breastfeeding infants.[86–89,197] In a clinical trial in Botswana, infants were randomized to 6 months of breastfeeding along with zidovudine prophylaxis, or to formula feeding with 1 month of zidovudine prophylaxis. HIV-free survival at 18 months was similar with both strategies.[197] Other studies evaluating extended antiretroviral prophylaxis to breastfeeding infants (with nevirapine alone or with nevirapine and zidovudine)[86–89] indicated that extended prophylaxis is efficacious in preventing breast milk transmission of HIV, with a longer duration of prophylaxis associated with a lower risk for mother-to-child transmission. Durations of extended infant antiretroviral prophylaxis ranged from 6 weeks to 6 months. The results of these studies led to the concept that, if infant antiretroviral prophylaxis will be used to prevent breast milk transmission of HIV, it should be used for the duration of breastfeeding. This idea is being evaluated in an ongoing clinical trial (PROMISE), which is being conducted at multiple sites around the world.

Prevention of HIV Transmission in Adolescents

Adolescents may have acquired HIV infection through mother-to-child transmission (already discussed) or can acquire through behaviors (e.g., sexual transmission or injection drug use). Prevention of behaviorally acquired HIV infection in adolescents is the focus of this section.

Essential components of the care of adolescents (Box 109.2) are counseling regarding behaviors that may put them at risk for acquisition of HIV and interventions to decrease the risk for transmission of HIV. In addition, adolescents should be educated regarding testing for HIV, pre-exposure prophylaxis, and postexposure prophylaxis. The most effective strategy for prevention of transmission of HIV in adolescents and adults will likely be to combine various types of interventions (behavioral and biological)

Box 109.2

Prevention of HIV Transmission in Adolescents

Counseling and education regarding *behaviors* that put them at risk for acquisition of HIV infection and interventions to decrease that risk

- Counseling and education regarding safer *sexual practices* and about sexually transmitted infections
- Counseling and education regarding prevention of initiation of *substance abuse* and prevention of HIV acquisition among those with an existing substance abuse problem

Screening for sexually transmitted infections

HIV testing

Pre-exposure prophylaxis

Postexposure prophylaxis

Sexual transmission accounts for most cases of HIV infection among adolescents and adults.[3] Although abstinence from sexual activity is the most effective means of avoiding acquisition of sexually transmitted infections (STIs), it is not possible to predict which adolescents will abstain. The AAP views provision of information regarding sex and STIs as an essential part of anticipatory guidance that pediatricians provide to their adolescent patients.[198] The AAP recommends that this information explicitly underscores the potential consequences of STIs, including HIV.[198] Adolescents with STIs, especially ulcerative diseases such as herpes simplex virus infection or syphilis, should be made aware of the association between such infections and transmission of HIV.[198] Screening for STIs in both public and private clinical settings represents an important component of prevention of HIV infection among adolescents and adults.[199]

Injection drug use or other percutaneous exposure to HIV is another important means of acquisition of HIV infection by adolescents and adults.[3] Adolescents should be informed about the dangers of injection drug use as well as precautions to decrease the risk for transmission of HIV and other bloodborne viral pathogens due to contact with blood or open wounds (e.g., during contact sports).[198,200] In addition to injection drug use or other percutaneous exposures, the use of noninjection drugs (e.g., alcohol, cocaine, marijuana) is associated with an increased risk for acquisition of HIV infection due to impaired judgment associated with the use of these substances, which in turn may increase the likelihood of unsafe sexual practices.[198] Efforts to reduce the risk for adolescents initiating substance abuse and to prevent acquisition of HIV infection among adolescents with a substance abuse problem should be encouraged.[201]

The CDC recommends at least annual testing for sexually active men who have sex with men between the ages of 13 and 64 years.[202] HIV testing is treated as part of routine care, and it is performed unless the patient objects ("opts out"). General consent for medical care is considered to encompass consent for HIV testing, and no specific consent for HIV testing would be required.[202] Testing for HIV infection is important in the prevention of HIV transmission because it provides the individual with knowledge of his or her HIV infection status, and, with this knowledge, most individuals reduce high-risk sexual behaviors.[203] In addition, testing is the first step in linking an HIV-infected person to appropriate care and treatment.

Antiretroviral therapy can be used to decrease the transmission of HIV. Lower plasma viral loads are associated with lower viral loads in genital secretions.[204–207] However, the concentrations of most antiretroviral agents vary among different fluids.[205–208] Associations between lower serum or genital viral loads and lower transmission rates among HIV serodiscordant heterosexual couples have been observed.[204,209,210] Ecologic studies of communities with high concentrations of injection drug users and of men who have sex with men suggest that increased use of antiretrovirals is associated with a decreased community viral load and a lower rate of new HIV infections.[211–213] In a trial of HIV-discordant couples, almost all heterosexual, HIV-infected sexual partners who were antiretroviral naïve and had $CD4^+$ counts between 350 and 550 cells/mm^3 were randomized to initiate or delay antiretroviral therapy.[214] Those who initiated antiretroviral therapy had a 96% decrease in transmission of HIV to uninfected partners. Suppression of viral load in blood and genital secretions with antiretroviral therapy should protect against transmission in other patient populations (e.g., men who have sex with men, injection drug users), but the effectiveness of such an intervention for groups other than heterosexual couples has not yet been established. The effectiveness of antiretroviral therapy in the prevention of transmission of HIV is predicated on the following: agents can effectively suppress viral loads in blood and genital fluids; adherence to therapy is high; and there is not a concomitant STI. Of note, when cART is available, rates of HIV risk behaviors may increase, sometimes substantially.[215]

Recommendations for postexposure prophylaxis in children and adolescents for nonoccupational exposure to HIV have been developed.[216] If postexposure prophylaxis is used, it should be initiated as soon as possible after exposure (no later than 72 hours) and continued for 28 days. Close follow-up is necessary to monitor adherence to and toxicity related to the prophylaxis, to provide psychological support, and to complete serial HIV testing.

Summary

HIV infection among children and adolescents in the US disproportionately affects minorities. Effective antiretroviral treatment and other care and support for HIV-infected children and adolescents have resulted in significantly decreased morbidity and mortality. Major successes have been achieved in prevention of mother-to-child transmission of HIV, but such transmission has not been eliminated. In addition, acquisition of HIV infection among adolescents and adults continues at an alarming rate. Essential components of the care of adolescents include HIV testing, counseling and education regarding behaviors that put them at risk for acquisition of HIV infection, and interventions to reduce that risk.

Immunopathogenesis of HIV-1 Infection

Grace M. Aldrovandi, Chiara Cerini, Nicole H. Tobin

In the absence of antiretroviral therapy, most human immunodeficiency virus type 1 (HIV-1) infections in children are due to mother-to-child transmission during pregnancy, birth, or breastfeeding. In settings where maternal HIV testing and treatment are available, most infections occur during adolescence (see Chapter 109) as a result of sexual activity or injection drug use. In this chapter we review the main features of HIV-1 immunopathogenesis, with an emphasis on the unique features of pediatric infection. We also describe how antiretroviral therapy (ART) allows preservation and reconstitution of immune function and alters the latent reservoir.

HIV Replication

Activated $CD4^+$ T lymphocytes represent the main cellular target of HIV-1, and most of these cells reside in the gastrointestinal tract. During acute infection, adolescents and adults frequently have nonspecific “viral” symptoms (see Chapter 111), but infants usually are symptom free.[1,2] In adolescents and adults, plasma viremia decreases and peripheral blood $CD4^+$ T-lymphocyte counts rise after a few weeks, even in the absence of ART. $CD8^+$ cytotoxic T lymphocytes (CTLs) play a major role in this early control of viral replication.[3–5] Additional adaptive immune responses, as well as innate immune responses, increasingly are being recognized as important factors in the control of initial viral replication.[6–8] After this acute period, adults and older children have relatively constant levels of viremia, which is referred to as a *set point*. This level of viremia is highly predictive of the later course of disease progression.[9,10]

In contrast to older children and adults, HIV-1-infected infants have high levels of plasma viremia and do not achieve a set point for several years.[11] These high and persistent levels of viremia are attributed to immunologic immaturity.[12,13] HIV-specific CTL responses can be detected at birth in infants infected in utero, but these responses are insufficient to control infection.[14] Studies suggest that this failure is due to decreased functional capacity, lack of CD4$^+$ T-lymphocyte help, and targeting of epitopes that inhibit the virus less effectively.[14,15] The relatively high frequency of regulatory T lymphocytes also may contribute to the suppression of virus-specific T-lymphocyte responses.[16,17] Other immune factors that may play a role include a decreased capacity of neonatal natural killer cells to mediate antibody-dependent cell-mediated cytotoxicity.

The availability of increased numbers of target cells also may contribute to the high level of viremia. The absolute number and relative percentage of CD4$^+$ T lymphocytes are much higher in infants and children.[18] Relative to their body size, the mass of the thymus is increased, and thymopoiesis is much more active during childhood.[19] Thus a large renewable source of CD4$^+$ T lymphocytes may serve as “fuel” for HIV infection and may account for the rapid tempo of disease progression observed in children.

Immune Consequences of Untreated HIV-1 Infection

CD4$^+$ T-lymphocyte depletion is the hallmark of HIV-1 infection. Direct infection leading to apoptosis by caspase-3 accounts for only 5% of this depletion. Approximately 95% of CD4$^+$ T lymphocytes die by caspase-1-mediated pyroptosis, a cellular defense mechanism in which nonproductive fragments of HIV-1 genomic

DNA activate a host DNA sensor, resulting in formation of an inflammasome. The inflammasome fragments nuclear DNA, secretes interferon 1β (attracting other CD4$^+$ T lymphocytes to their fiery death), and ruptures the cell.[20,21] Other potential mechanisms of CD4$^+$ T-lymphocyte depletion include decreased production of bone marrow precursors and thymic dysfunction. The function and repertoire of the remaining CD4$^+$ T lymphocytes are significantly perturbed, resulting in defects in both B-lymphocyte antibody formation and the generation of effective CD8$^+$ T-lymphocyte responses.[22–25] Other immune cell perturbations in HIV-1 infection are shown in Box 110.1.

Box 110.1

Immunopathologic Consequences of HIV-1 Infection

T Lymphocytes

Laboratory Manifestations

Lymphopenia

Selective CD4$^+$ T-lymphocyte depletion

Decreased CD4$^+$/CD8$^+$ T-lymphocyte ratio

Impairments in other T-lymphocyte subsets (Th17 and Treg depletion; switch Th1→Th2-type response) and gamma-delta cells

Impaired Functions

Impaired delayed-type hypersensitivity (new and recall)

Impaired mitogen-antigen responses

Impaired alloantigen reactivity

Impaired T-lymphocyte cytotoxicity

Impaired cytokine production (IL-2, IFNγ, others)

Clinical Manifestations

Chronic active viral infections (i.e., varicella-zoster virus, cytomegalovirus, Epstein-Barr virus)

Neoplasms

B Lymphocytes

Phenotypic Perturbations

Overrepresentation of activated, exhausted, and terminally differentiated B lymphocytes

Overrepresentation of immature/transitional B lymphocytes

Reduced representation of $CD27^+$ memory B lymphocytes

Impaired Functions

Polyclonal B-lymphocyte activation

Hypergammaglobulinemia

Polyclonal immunoglobulin class switch recombination (switch from IgM to nonprotective IgG, IgA, and IgE)

Impaired antibody responses (primary and secondary responses; T-lymphocyte-dependent and T-lymphocyte-independent antigens)

Reduced proliferative capacity

Stunted immunoglobulin diversification

Increased circulating immune complexes

Loss of serologic antibody memory

Clinical Manifestations

Impaired vaccine responses

B-lymphocyte malignancies

Autoimmune diseases

Monocytes and Macrophages

(including bone marrow precursors and microglial cells in the central nervous system)

Laboratory Manifestations

Increased levels of circulating “pocked” red blood cells

Elevated serum levels of TNF

Impaired splenic clearance (antibody-coated red blood cells)

Impaired Functions

Noncytopathic latent infection

Impaired delayed-type hypersensitivity

Impaired granuloma formation

Clinical Manifestations

Opportunistic infections (mainly mycobacterial)

Invasive pneumococcal infections

HIV-associated encephalopathy

Natural Killer Lymphocytes

Laboratory Manifestations

Reduced percentage of NK cells

Depletion of mature cytotoxic NK cell subsets (CD161$^+$, CD56$^+$, or CD16$^+$)

Selective depletion of invariant NKT lymphocytes

Impaired Functions

Impaired cytolytic activity

Impaired immunoregulatory activity (DC-mediated helper function for Th1 and CTL responses)

Clinical Manifestations

Chronic viral infection (i.e., herpesvirus)

Neoplasms

Dendritic Cells

Laboratory Manifestations

Decreased numbers of both plasmacytoid and myeloid DCs in peripheral blood

Impaired Functions

Impaired IFNα production

Increased secretion of inflammatory cytokines and chemokines (including TNF and IL-6)

Neutrophils

Laboratory Manifestations

Neutropenia

Impaired Functions

Impaired chemotaxis and expression of cellular adhesion molecules

Impaired phagocytosis

Impaired production of toxic oxygen species

Clinical Manifestations

Opportunistic bacterial and fungal infections

CTL, cytotoxic T lymphocyte; DC, dendritic cell; Ig, immunoglobulin; IL, interleukin; IFN, interferon; NK, natural killer; NKT, natural killer T; Th, T helper; TNF, tumor necrosis factor; Treg, regulatory T lymphocyte.

Destruction of up to 60% of CD4$^+$ T lymphocytes residing in the gastrointestinal tract has been identified as a critical early event in HIV-1 pathogenesis.[26–31] Unlike their counterparts in the blood, the numbers of these cells in the gastrointestinal tract do not recover after the acute phase, and even with ART, their numbers rarely are restored.[32–34] Most of the CD4$^+$ T lymphocytes destroyed in the gut belong to the recently identified Th17 subset.[35–37] These cells regulate responses to bacterial and fungal pathogens at mucosal surfaces. This loss is associated with increased microbial translocation and immune activation, which contribute to enhanced HIV spread and CD4$^+$ T-lymphocyte loss.[38,39]

The chronic phase of HIV-1 infection is characterized by a pathologic activation of the immune system. The extent of immune activation predicts disease progression better than either plasma viremia or CD4$^+$ T-lymphocyte counts.[40,41] This activation is linked to immune exhaustion, impaired T-lymphocyte homeostasis, hypergammaglobulinemia, and other perturbations that result in increased susceptibility to opportunistic infections and cancers that characterize AIDS.[42,43]

Effects of Antiviral Therapy on Immune Function and Viral Reservoirs

The advent of effective ARTs has transformed HIV-1 infection into a chronic manageable disease. Higher levels of plasma viremia, variable pharmacokinetics, and poor adherence to therapy offer unique challenges to HIV-1 suppression in children. Nevertheless, with contemporary regimens, most children can achieve viral suppression with corresponding improvements in immune function. Normalization of both T- and B-lymphocyte numbers and function has been documented in many studies, particularly if therapy is initiated early in infection.[44–51] In contrast to adults, some infants who achieve and maintain viral suppression in the first few months of life do not develop detectable HIV-specific responses (antibodies, $CD4^+$, and CTL responses).[44,52] These infants mount appropriate responses to vaccines and viral infections, suggesting that this defect is specific to HIV-1. Increased thymic function also confers an advantage in HIV-infected adolescents.[53] Children who start therapy at low $CD4^+$ T-lymphocyte levels may not experience full immunologic recovery.[35]

Early infant treatment modifies clinical disease progression, and ART also can influence both the size and composition of latent viral reservoirs. An important barrier to HIV eradication is the early seeding of long-term reservoirs. HIV persists in multiple memory T-lymphocyte subsets with varying half-lives and modes of maintenance, which contribute to the latent reservoirs to varying degrees.[54] T-lymphocyte subset composition differs in infants and children.[55] Because very early treatment in adults alters which T-lymphocyte subsets make up the reservoir, it is likely that very early treatment in infants, which decreases the size of reservoirs, also can alter its composition.[56–58] The recent case of an HIV-infected infant who, after 18 months of very early ART, remained aviremic without ART for 27 months (rather than the typical days to weeks) before experiencing viral rebound, is encouraging and currently is under investigation in clinical trials.[59–62]

Notably, at the initiation of ART, between 10% and 40% of individuals develop a pathologic immune response to antigens, especially latent or persistent mycobacterial and cryptococcal infection.[63–65] This acute inflammatory condition is referred to as *immune reconstitution inflammatory syndrome* (IRIS). It is similar to "paradoxical reactions" long recognized in *Mycobacterium tuberculosis* infection. It is more common in individuals with low $CD4^+$ T-lymphocyte levels, and recent data suggest that infants may be at greater risk.[66,67] Most individuals can be managed by the use of anti-inflammatory agents without interrupting ART.

Diagnosis and Clinical Manifestations of HIV Infection

Paul Krogstad

Most cases of human immunodeficiency virus (HIV) infection in infants and young children result from mother-to-child transmission. Infection acquired by sexual contact and injectable drug use contributes to the growing number of infections in adolescents and young adults. The early clinical manifestations of HIV infection are varied and sometimes indistinct, particularly in infants and young children. Early diagnosis is a prerequisite to timely provision of effective antiretroviral therapy and potentially life-saving prophylactic medications. Accurate detection of HIV infection in children younger than 18 months rests on specialized laboratory testing to detect the virus itself, owing to the confounding effects of transplacentally acquired maternal antibody. This chapter outlines diagnostic approaches for HIV infection in infants, children, and adolescents and young adults and provides an overview of the pathologic effects of HIV on various organ systems seen in these age groups. Infectious complications of HIV infection are discussed in Chapter 112.

Diagnosis

Most HIV infections in infants and children are acquired through mother-to-child transmission of the virus in utero, during labor and delivery, or postnatally during breastfeeding. Transplacentally acquired antibodies specific for HIV are present in the serum of newborns born to infected women, yielding positive serologic tests regardless of whether infection has actually occurred. Because seroreversion usually does not occur until 12 to 18 months of age, and may not occur until 24 months of age, the diagnosis of HIV infection in infants must be based on virologic tests. Virus culture has been used in the past but is slow and technically cumbersome. Instead, detection of HIV RNA or DNA by polymerase chain reaction (PCR) or other nucleic acid tests (NATs) is recommended by the World Health Organization (WHO) and public health authorities and experts in the United States.[1–3] WHO also endorses the use of specialized ultrasensitive enzyme immunoassay (EIA) methods to detect the HIV p24 protein in plasma or dried blood spots because this method is less expensive and more readily available in some resource-poor settings.[3]

The sensitivity of DNA PCR detection of HIV in blood leukocytes is about 55% at birth, increases to more than 90% by 2 to 4 weeks of age, and approaches 100% by 3 months of age. False-positive tests are rare after the immediate newborn period, with a reported specificity of 100% thereafter.[1,4–6]

HIV RNA assays detect the presence of the viral genome in plasma. The specificity of HIV RNA assays for diagnosis of viral infection is essentially 100%. Using a threshold of 5000 copies/mL of plasma as a minimal threshold for positivity, the sensitivity of HIV RNA assays for detection of infection in infants is 25% to 58% during the first several weeks of life, 89% at age 1 month, and 90% to 100% by age 2 to 3 months. HIV RNA testing should be sensitive despite antiretroviral therapy. The impact of maternal therapy or postnatal treatment of infants on the sensitivity of HIV RNA tests remains the subject of investigation due to continuous changes in the composition and potency of the antiretroviral agents used.[1,2]

For infants born to HIV-infected mothers, the US Public Health Service recommendations include HIV DNA PCR or HIV RNA NAT testing at 14 to 21 days, 1 to 2 months, and 4 to 6 months of age.[2] Some experts also recommend testing immediately after birth for infants whose mothers have poorly controlled HIV disease and other infants at higher risk for acquiring infection. Cord blood specimens should not be used for HIV RNA or DNA testing because contamination of specimens with maternal blood may cause false-positive results. Any positive virologic test should be confirmed as soon as possible by a test on a second specimen. An HIV RNA assay can be used as the confirmatory test for infants who have an initial positive HIV DNA PCR test.[2]

HIV infection is *presumptively* excluded in nonbreastfed infants who have had two or more negative virologic tests, with one test obtained at ≥14 days of age and the other obtained at ≥4 weeks of age. Children with one negative virologic test result obtained at ≥2 months of age also are presumed to be uninfected. *Definitive* exclusion of HIV infection in a nonbreastfed infant requires two or more negative virologic tests, with one obtained at ≥1 month of age and the other at ≥4 months of age. Ideally, these tests to exclude HIV infection should have been performed 2 to 4 weeks after cessation of any antiretroviral prophylaxis.[2]

The worldwide genetic variability of HIV has an impact on the choice of nucleic acid tests used for diagnosis and monitoring of infection. HIV exists in a variety of genetically distinguishable subtypes.[7] Subtype B is the predominate variant found in North America, South America, and Western Europe. Subtype C is the major subtype in most of sub-Saharan Africa and India, and a recombinant variant of HIV, CRF01, predominates in Southeast Asia. HIV DNA tests used in the United States will not detect all non-B subtypes of HIV. HIV RNA assays are more sensitive for detecting non−subtype B HIV and should be preferentially used when infection is thought to have originated in Asia or Africa. These technical limitations of HIV nucleic acid testing, and the possibility of infection with HIV-2, should be kept in mind if the clinical presentation of a child leads to concerns about undiagnosed HIV infection. Unexpected cases of non−subtype B HIV have been documented in the US.[8,9]

The diagnosis of HIV infection in children older than 24 months, adolescents, and adults primarily relies on HIV antibody tests or on antigen-antibody combination tests that also detect the viral p24 HIV-specific antigen (Table 111.1). The recommended schema for diagnostic evaluation of patients 24 months or older is outlined in Fig. 111.1.[10] In brief, testing should begin with a combination immunoassay that detects HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen. An immunoassay to detect HIV-1/2 antibodies is an alternative, but the combination assay permits detection of infection before antibody responses to HIV antigens have developed. All specimens reactive on this initial assay should then undergo supplemental testing with an immunoassay that differentiates HIV-1 from HIV-2 antibodies. Specimens that are reactive on the initial immunoassay and nonreactive or indeterminate on the antibody differentiation assay proceed to HIV-1 nucleic acid testing to resolve the diagnostic ambiguity. Additional testing, including HIV-1 viral RNA measurement and $CD4^+$ T-lymphocyte quantitation, are then recommended to determine the need for prophylactic therapy against opportunistic infections and in preparation for institution of antiretroviral therapy.[2]

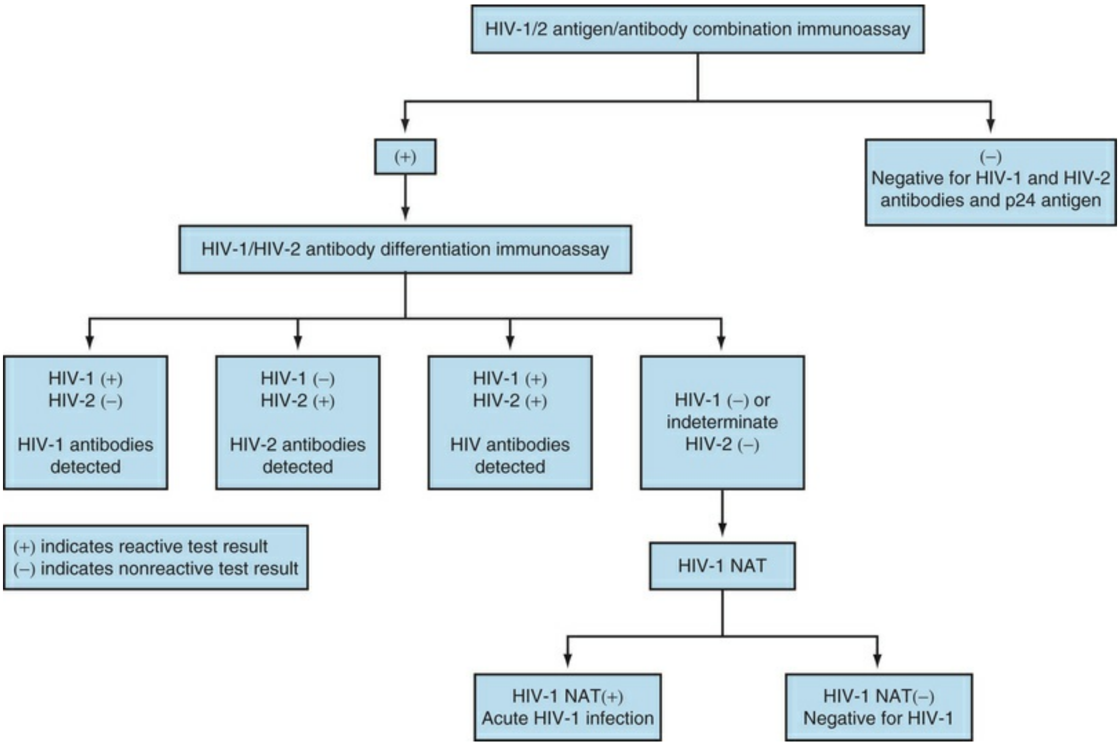
TABLE 111.1

Assays to Detect HIV Infection

Assay	Type	Advantages	Disadvantages
PCR and other NATs to detect HIV DNA and RNA	Virologic	Very highly sensitive	Small risk for false-positive results if HIV RNA value <5000 copies/mL is considered positive
Ultrasensitive p24 antigen detection assays for plasma/dried blood spots	Virologic	Inexpensive	Less sensitive than NAT; false-positive results in the first week of life
Culture	Virologic	Sensitive, highly specific	Requires weeks to complete, technically complex; research use only. Not currently recommended for diagnosis.
Ultrasensitive p24 antigen detection assays for plasma/dried blood spots	Virologic	Inexpensive	Less sensitive than NAT; false-positive results in the first week of life
HIV-1/2 antibody/HIV-1 antigen combination immunoassays	Virologic and antibody Based	Sensitive, highly specific. Detection of antigen allows early diagnosis before an individual develops HIV antibody.	Recommended for initial testing to screen for established infection with HIV-1 or HIV-2 and for acute HIV-1 infection.
HIV-1/2 immunoassays	Antibody	Highly sensitive	Alternative for initial testing
HIV-1 Western blot and HIV-1 indirect	Antibody		Technically more difficult than immunoassay methods.

IFAs			Recommended as an alternative for supplemental testing. Will not detect acute HIV infection.
HIV-1/HIV-2 antibody differentiation immunoassay	Antibody	Used to clarify ambiguous results from HIV-1/2 combination assays	Recommended for supplemental testing.

IFA, immunofluorescence assay; NAT, nucleic acid testing; PCR, polymerase chain reaction.



HIV-1/2 antigen/antibody combination immunoassay
(+)
(–)
Negative for HIV-1 and HIV-2 antibodies and p24 antigen
HIV-1/HIV-2 antibody differentiation immunoassay
HIV-1 (+)
HIV-2 (–)
HIV-1 antibodies detected
HIV-1 (–)
HIV-2 (+)
HIV-2 antibodies detected
HIV-1 (+)
HIV-2 (+)
HIV antibodies detected
HIV-1 (–) or indeterminate
HIV-2 (–)

HIV-1 NAT(+)
Acute HIV-1 infection
HIV-1 NAT(–)
Negative for HIV-1

FIGURE 111.1 Schema for diagnosis of HIV infection in children older than 24 months, adolescents, and adults. NAT, nuclear acid test.

Several rapid tests also are available to detect HIV antibody in blood specimens collected by fingerstick or by venipuncture. These tests are useful for point-of-care testing because the results of rapid tests are available promptly, thereby enhancing the effectiveness of posttest counseling.[10] Rapid tests also facilitate the determination of HIV status of pregnant women, allowing the timely administration of antiretroviral therapy to prevent mother-to-child transmission at the time of delivery.[5] Individuals with positive (reactive) rapid tests should be evaluated as in Fig. 111.1, beginning with an antigen/antibody combination immunoassay. In areas with a high prevalence of HIV, a second enzyme immunoassay (EIA) or use of a rapid diagnostic test may be an acceptable approach for confirmation of an EIA or an initial rapid test result.[3,11] However, rapid tests, like other antibody tests, will yield false-positive results in uninfected infants and toddlers with maternally derived HIV antibody.

Some experts confirm the absence of HIV infection after ≥12 months of age in children with prior negative virologic tests by performing an antibody test to document loss of maternal HIV antibodies.[2] Two or more negative HIV antibody tests from separate specimens obtained at ≥6 months of age also allow infection to be excluded, if an infant has not been breastfed. If breastfeeding has occurred, HIV infection cannot be definitively excluded until the infant has a negative diagnostic test ≥6 weeks after breastfeeding has ceased.[2]

Early Signs, Symptoms, and Laboratory Abnormalities After Mother-to-Child Transmission

Infants born to HIV-infected women are more often of low birth weight than unexposed infants but have normal physical findings and are symptom free during the neonatal period. The earliest manifestations of HIV infection in infants frequently are nonspecific.[12,13] Lymphadenopathy, often associated with hepatosplenomegaly, is a commonly observed early sign. Oral candidiasis, parotitis, poor weight gain, dermatitis, developmental regression, or failure to achieve developmental milestones are other common presenting features. Before prophylactic therapy with trimethoprim-sulfamethoxazole and other agents became routine, *Pneumocystis jirovecii* pneumonia (PCP) accounted for about half of all AIDS-defining conditions diagnosed during the first year of life in the US.[14]

Laboratory abnormalities indicative of immunologic derangement also are seen in infancy. By 1 or 2 months of age, many HIV-infected infants have $CD4^+$ lymphocyte counts that are significantly lower than those in HIV-exposed, uninfected infants.[15] Hyperimmunoglobulinemia G, A, E, or M is present in up to 90% of HIV-infected infants by 6 months of age.[13,16]

The Centers for Disease Control and Prevention (CDC) recently revised surveillance staging of disease (Table 111.2). This classification ranges from stage 1 (mild abnormality in $CD4^+$ T-lymphocyte parameters) to stage 3 (laboratory evidence of substantial immunodeficiency). An individual also is said to have stage 3 disease, regardless of $CD4^+$ T-lymphocyte parameters, if they have experienced an AIDS defining illnesses (Box 111.1).[17] The WHO clinical classification of HIV infection is similar in concept and ranges from stage 1 (symptom free) to stage 4 (advanced symptoms).[18]

TABLE 111.2

HIV Infection Stage Based on Age-Specific $CD4^+$ T-lymphocyte Count or $CD4^+$ T-Lymphocyte Percentage of Total Lymphocytes

Stage[a]	Age at Which $CD4^+$ T Lymphocytes Tested					
	<1 yr		1–5 yr		≥6 yr	
	Cells/mm^3	%	Cells/mm^3	%	Cells/mm^3	%
1	≥1500	≥34	≥1000	≥30	≥500	≥26
2	750–1499	26–33	500–999	22–29	200–499	14–25
3	<750	<26	<500	<22	<200	<14

[a] The stage is based primarily on the $CD4^+$ T-lymphocyte count; the $CD4^+$ T-lymphocyte count takes precedence over the $CD4^+$ T-lymphocyte percentage, and the percentage is considered only if the count is missing.

From Centers for Disease Control and Prevention. Revised surveillance case definition for HIV infection—United States, 2014. MMWR Recomm Rep 2014;63(RR-3):1–10.

Box 111.1

Stage 3–Defining Opportunistic Illnesses in HIV Infection

Bacterial infections, multiple or recurrent[a]

Candidiasis of bronchi, trachea, or lungs

Candidiasis of esophagus

Cervical cancer, invasive[b]

Coccidioidomycosis, disseminated or extrapulmonary

Cryptococcosis, extrapulmonary

Cryptosporidiosis, chronic intestinal (>1 month's duration)

Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month

Cytomegalovirus retinitis (with loss of vision)

Encephalopathy attributed to HIV[c]

Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis with onset at age >1 month

Histoplasmosis, disseminated or extrapulmonary

Isosporiasis, chronic intestinal (>1 month's duration)

Kaposi sarcoma

Lymphoma, Burkitt (or equivalent term)

Lymphoma, immunoblastic (or equivalent term)

Lymphoma, primary, of brain

Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary

Mycobacterium tuberculosis of any site, pulmonary,[b] disseminated, or extrapulmonary

Mycobacterium, other species or unidentified species, disseminated or extrapulmonary

Pneumocystis jirovecii (PCP) pneumonia

Pneumonia, recurrent[b]

Progressive multifocal leukoencephalopathy

Salmonella septicemia, recurrent

Toxoplasmosis of brain with onset at age >1 month

Wasting syndrome attributed to HIV[c]

---

[a] Only among children aged <6 years.

[b] Only among adults, adolescents, and children aged ≥6 years.

[c] Suggested diagnostic criteria for these illnesses, which might be particularly important for HIV encephalopathy and HIV wasting syndrome, are described in the following references: Center for Disease Control and Prevention. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR Recomm Rep 1994;43(RR-12); and Centers for Disease Control and Prevention. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR Recomm Rep 1992;41(RR-17).

Organ System–Specific Manifestations of HIV Infection

HIV infection has the potential to cause injury directly or indirectly to many organ systems. The following sections summarize the most common manifestations of HIV infection and AIDS in infants, children, and adolescents.

Neurologic Manifestations

Central nervous system (CNS) pathology and neurocognitive dysfunction are extremely common in untreated HIV-infected children.[19–21] Before the availability of antiretroviral therapy, progressive HIV encephalopathy accounted for about 15% of all pediatric AIDS-defining conditions reported to the CDC.[22]

Clinical features of HIV-associated encephalopathy in young children are shown in Table 111.3. Developmental delay or loss of developmental milestones are common manifestations and may be associated with poor weight gain. Characteristic computed tomography (CT) and magnetic resonance imaging findings in such children include cerebral atrophy (85%–100% of cases) and bilateral symmetric calcification of the basal ganglia (15%–40% of cases)[21,23,24] (Fig. 111.2). Evidence of cerebrovascular disease can be seen, and strokes occur in a small fraction of children.[25] Results of cerebrospinal fluid (CSF) studies usually are normal; mild pleocytosis is observed in some cases.[26]

TABLE 111.3

Features of Encephalopathy Associated With Human Immunodeficiency Virus Infection in Infants and Children

Clinical Features	**Neuroimaging Features**
Impaired brain growth/microcephaly	Cerebral atrophy
Developmental delay or regression Expressive language impairment Spastic weakness	Symmetric calcifications in basal ganglia
Pathologic reflexes	
Dystonia	
Gait disturbance	

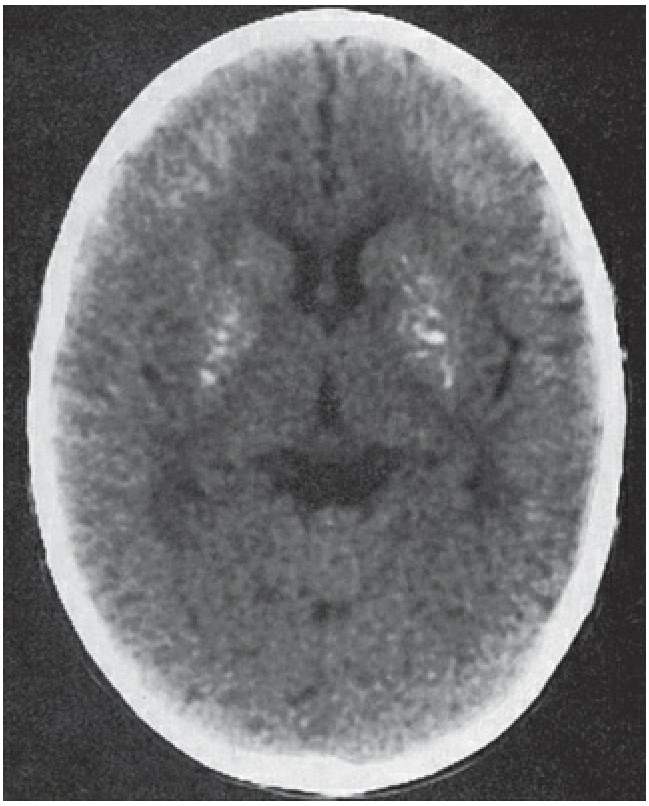

FIGURE 111.2 Computed tomography scan of the brain showing bilateral symmetric calcification of the basal ganglia in a 2-year-old boy with vertically acquired HIV infection.

HIV-related neuropathology is likely the result of HIV infection rather than from complicating infection or malignancy. Evidence supporting this view includes virus isolation from or detection of RNA by PCR in the CSF, intrathecal synthesis of HIV antibody, and identification of HIV nucleotide sequences in brain tissue at autopsy.[26–30] Neuropathologic features noted in the brains of HIV-infected children include atrophy, subcortical inflammatory lesions, multinucleated giant cells, and vascular calcification[27,29]

Blood-derived macrophages, resident microglia, their derivatives (including multinucleated giant cells), and astrocytes are the only cells that consistently have been shown to harbor HIV in the CNS.[20,27,31] It is hypothesized that activation of these cells by HIV results in overproduction of certain cytokines, arachidonic acid metabolites, nitric oxide, and quinolinic acid, which in turn may be responsible for some of the neuropathologic changes.[32–35] Elevated serum concentration of tumor necrosis factor-α (TNF-α) has been associated with progressive encephalopathy in HIV-infected children,[33–35] and TNF-α can produce white-matter destruction in vitro similar to that observed clinically and pathologically in children with encephalopathy.[36] Platelet-activating factor and products of arachidonic acid metabolism also may mediate CNS injury, possibly through upregulation of TNF-α or other cytokines.[37]

The rate of progression and severity of HIV encephalopathy vary tremendously and are modified by antiretroviral therapy. The effectiveness of antiretroviral therapy in preventing or reversing CNS abnormalities may depend on the CNS penetration of the specific agents used and how early therapy is begun, although conflicting data are reported.[23,38]

Residual behavioral problems, as well as neurologic, cognitive, and scholastic impairments, still appear to be common with current antiretroviral therapy, and some antiretroviral drugs have been associated with neuropsychiatric symptoms.[23,38] Consequently, frequent evaluation of developmental milestones, neuropsychological testing, counseling, and supportive and symptomatic care are critical in the care of HIV-infected children.[2]

Pulmonary Conditions

Before the development of multidrug antiretroviral therapy, lymphoid interstitial pneumonia (LIP) and the clinically similar, but histologically distinct, pulmonary lymphoid hyperplasia (PLH) were second only to PCP as pulmonary diseases indicative of HIV infection and AIDS in children.[22] Although LIP and PLH no longer are considered AIDS-defining illnesses because of their relatively benign course, one retrospective study showed twice the rate of hospitalization due to serious respiratory infections in patients with LIP-PLH than in HIV-infected children who did not have evidence of LIP-PLH.[39]

Although the radiographic features of LIP-PLH and PCP can be similar, clinical features distinguish the conditions (Table 111.4). The onset of LIP-PLH usually is insidious. Cough and tachypnea often are present. Examination of the chest generally reveals few auscultatory abnormalities. Marked generalized lymphadenopathy, hepatosplenomegaly, and salivary gland, especially parotid gland, enlargement may be noted. Digital clubbing is observed in advanced cases of LIP-PLH. A chest radiograph typically reveals symmetric bilateral reticulonodular and interstitial infiltrates, sometimes in association with hilar adenopathy (Fig. 111.3). Differentiation from miliary tuberculosis sometimes is difficult, although patients with LIP-PLH are more likely to be afebrile and relatively well appearing, and the chest radiograph shows less distinct (sometimes larger) lesions and more interstitial abnormality than in tuberculosis. There is no typical laboratory abnormality, but a marked increase in serum immunoglobulin concentrations often is present in patients with LIP-PLH, reflecting the presence of immunologic activation.

TABLE 111.4

Clinical Differentiation of LIP-PLH from PCP Pneumonia

Finding	LIP-PLH	PCP
CLINICAL		
Acute onset	No	Yes
Fever	No	Yes (usually)
Retractions	Late	Early
Crackles	No	Yes
Hypoxia	Late	Early
Clubbing	Yes	No
Salivary gland enlargement	Yes	No
BAL FLUID		

Lymphocyte predominance	Yes	No
Neutrophil predominance	No	Yes

BAL, bronchoalveolar lavage; LIP-PLH, lymphoid interstitial pneumonitis or pulmonary lymphoid hyperplasia; PCP, *Pneumocystis jirovecii* pneumonia.

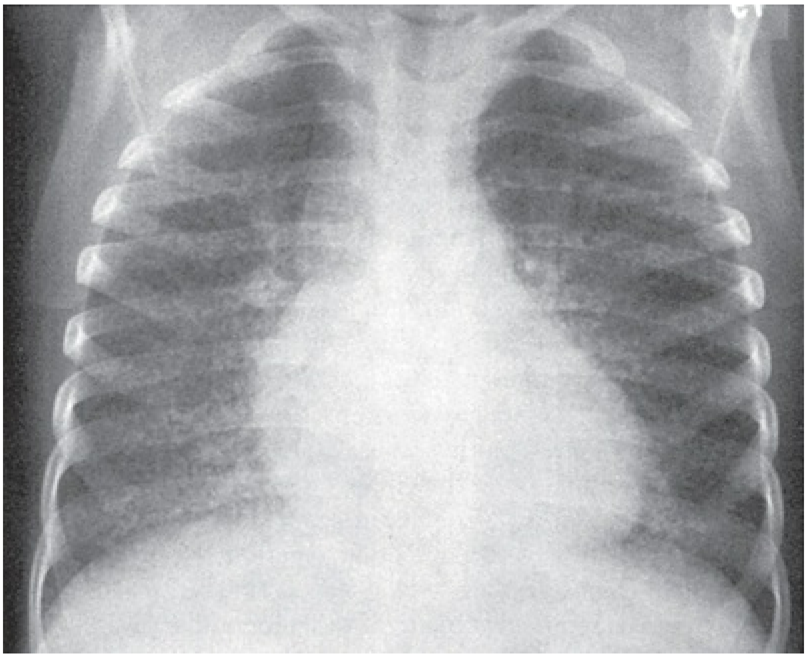

FIGURE 111.3 Chest radiograph demonstrating bilateral reticulonodular interstitial infiltrates of lymphoid interstitial pneumonitis/pulmonary lymphoid hyperplasia in a 4-year-old boy with vertically acquired HIV infection.

With careful evaluation to exclude tuberculosis or other infections, a presumptive diagnosis of LIP-PLH can be made on the basis of characteristic radiographic features persisting for 2 months or longer; CT can enhance diagnostic evaluation.[39,40] A definitive diagnosis requires lung biopsy. Histopathologic and immunocytochemical analyses reveal a mononuclear interstitial infiltrate surrounding the airways composed of immunoblasts, plasma cells, and $CD8^+$ lymphocytes. The pathogenesis of LIP-PLH is poorly understood, but Epstein-Barr virus (EBV) has been repeatedly implicated as a cofactor because EBV nucleic and antigens are frequently detected in histologic sections.[41]

The clinical course of LIP-PLH is variable. Spontaneous clinical remission sometimes is observed. In severe cases, there is progressive hypoxia and respiratory failure. Exacerbation of clinical signs and symptoms can occur in association with intercurrent viral respiratory illnesses. Antiretroviral treatment is associated with clinical improvement, including full resolution.[42] Supportive care is essential, including immunization against common viral and bacterial pathogens (e.g., influenza virus, *Streptococcus pneumoniae*), which often complicate LIP, and appropriate use of antibiotics and antiviral drugs for acute infections.[39] Some patients require supplemental oxygen, and anecdotal reports suggest that some cases with progressive hypoxemia may respond to systemic corticosteroid therapy.[40,43]

Malignancy

Cancers are uncommon among HIV-infected children but occur at much higher rates than in the general population.[44] Malignancy is most common among children with severe immunosuppression and in those who had been receiving multidrug antiretroviral therapy for 2 years or less.[44] The most common cancer is non-Hodgkin lymphoma (Burkitt or immunoblastic types).[45–47] Patients often manifest fever, weight loss, and evidence of "extranodal" disease (e.g., hepatomegaly and jaundice, abdominal distention, myelophthisis, or neurologic abnormalities). Children with CNS lymphoma can have delay or loss of developmental milestones, cranial nerve palsies, seizures, or hemiparesis.[48] Contrast-enhanced CT of the brain reveals hyperdense periventricular mass lesions similar to those seen in cerebral toxoplasmosis. CNS lymphoma more commonly causes an isolated brain mass in children than toxoplasmosis or other infectious agents. In addition to elevated protein and depressed glucose concentrations, examination of CSF can reveal malignant cells. Brain biopsy for definitive diagnosis is indicated for those children who have rapidly progressive disease or clinical or radiographic progression despite empiric therapy for toxoplasmosis.

The pathogenesis of AIDS-associated non-Hodgkin lymphoma is poorly defined; both EBV and mutations or rearrangements in the *c-myc* oncogene have been implicated.[49–51] Effective chemotherapeutic regimens are available.[52]

Hodgkin lymphoma, leiomyosarcoma, leiomyoma, and Kaposi sarcoma also occur with greater frequency in children with HIV infection than in the general population.[52] A strong association exists between EBV and leiomyosarcoma or leiomyoma. Endobronchial leiomyosarcoma or leiomyoma can manifest with fever or cyanosis.[47] Multiple pulmonary parenchymal nodules can be visualized radiographically. Clinical manifestations of pulmonary Kaposi sarcoma, which is triggered by infection with human herpesvirus 8, include fever, cough, dyspnea, and hemoptysis. The radiographic features are diffuse reticulonodular infiltrates resembling those seen in LIP-PLH or PCP. Kaposi sarcoma also can present with involvement of lymph nodes, the oral cavity (hard palate or tonsils), or skin. Gastrointestinal lesions can occur with any of these malignancies, resulting in gastrointestinal bleeding, abdominal pain, or bowel obstruction.[46,47]

Gastrointestinal Disease

Wasting Syndrome

In some areas of Africa, HIV infection was originally referred to as “slim disease.”[53] Weight loss, or failure to gain appropriate weight, is a common presenting symptom in HIV-infected infants and children and may appear within the first 2 to 3 months of life.[54] Several factors contribute to wasting. HIV infection itself increases a child's nutritional requirements. In addition, opportunistic infections, especially those associated with fever, contribute to increased metabolic requirements. Oral lesions (e.g., thrush, herpes simplex virus infection, recurrent aphthous ulcers) can interfere with feeding. Chronic diarrhea and malabsorptive syndromes can inhibit caloric uptake. Effective antiretroviral therapy and nutritional support are the primary approaches to treating wasting syndrome and can include the use of nasogastric or gastrostomy tube feedings in some cases.

Hepatitis

Hepatomegaly, moderate increases in serum concentrations of hepatic enzymes (e.g., 5- to 10-fold increases in aspartate aminotransferase and/or alanine aminotransferase), are common in HIV-infected children but often are unaccompanied by clinical manifestations.[55] The differential diagnosis of hepatitis in HIV-infected children is broad and includes a variety of infectious causes, neoplasms, and effects of medications (Box 111.2).[56] In addition, elevation of transaminase concentrations has been reported in association with the use of virtually all antiretroviral medications.[2] These elevations usually are clinically insignificant in children but can necessitate discontinuation of antiretroviral medications in some cases. The clinical course of HIV-associated hepatitis is variable. Histopathologic studies of liver tissue obtained from HIV-infected children have identified giant cell transformation of hepatocytes, fatty degeneration, and lymphoplasmacytic infiltration as prominent features.[57,58] Coinfection with HIV can hasten the progression of liver disease caused by hepatitis B or C. The presence of hepatitis B coinfection also influences the selection of antiretroviral medications because worsening of liver disease can occur with discontinuation of antiretroviral agents that have activity against hepatitis B virus.[59]

Box 111.2

Differential Diagnosis of Hepatitis in Children Infected With HIV

Infection

Bacteria (e.g., *Mycobacterium avium* complex, *Mycobacterium tuberculosis,* or *Bartonella* spp.–induced bacillary peliosis hepatis)

Viruses (e.g., hepatitis A, B, or C; cytomegalovirus; Epstein-Barr virus; herpes simplex virus; adenovirus; or HIV)

Fungi (e.g., *Candida* spp., *Cryptococcus neoformans, Histoplasma capsulatum, Pneumocystis jirovecii*)

Protozoans (e.g., *Toxoplasma gondii*)

Malignancy

Lymphoma

Sarcoma

Drug-Induced

Sulfonamides

Antiretroviral agents (especially nonnucleoside reverse transcriptase inhibitors, tipranavir)

Antimycobacterial medications

Pentamidine

Cardiovascular Disease

Cardiac abnormalities are commonly observed in untreated HIV-infected children. Electrocardiographic abnormalities include conduction defects, unexplained sinus tachycardia, voltage abnormalities compatible with chamber enlargement, and dysrhythmias. Echocardiographic findings include ventricular dysfunction and pericardial effusion.[60] Many abnormalities are not apparent clinically, but in one retrospective study of 81 HIV-infected children, serious dysrhythmia, congestive heart failure, and unexpected cardiac arrest occurred in 28 (35%), 8 (10%), and 7 (9%) patients, respectively.[61]

The pathogenesis of cardiac disease in HIV-infected children is poorly understood, but epidemiologic associations between coinfection with EBV and bradycardia and congestive heart failure have been reported.[61] Adenovirus and cytomegalovirus gene sequences have been identified in a postmortem study of cardiac tissue from HIV-infected children with myocarditis, suggesting a possible etiologic role.[62] Rare cases exist in which HIV-infected cells were demonstrated in the myocardium.[63] The relationship between antiretroviral agents and cardiomyopathy remains unclear. Antiretroviral therapy has been associated with a marked reduction in the risk for cardiomyopathy, and infected children with cardiomyopathy and congestive heart failure generally improve with antiretroviral therapy and specific management of the cardiac disease. The use of either zalcitabine, an obsolete antiretroviral medication, or zidovudine has been linked to the development of cardiomyopathy.[64] Abnormalities of serum lipid concentrations and effect on electrocardiographic findings are adverse effects of antiretroviral medications, especially the HIV protease inhibitors. When dyslipidemia is encountered, changes in diet and other lifestyle modifications, substitution of other medications, or pharmacologic treatment may be needed.[2]

Renal Dysfunction

Nephropathy was initially described among children with advanced HIV disease.[65–67] In one early study, progressive renal disease with nephrotic syndrome and renal failure developed in 5 of 12 children with AIDS and proteinuria.[67] Persistent proteinuria now is recognized as a common finding and can be the initial evidence of renal disease in HIV-infected children and adolescents.[65,68,69] Most frequently, renal biopsies reveal histopathologic evidence of HIV-associated nephropathy (HIVAN), a collapsing form of focal and segmental glomerulosclerosis with microcystic tubulointerstitial injury. In vitro and in vivo studies suggest that HIV infection of renal epithelial parenchymal cells is involved in the development of HIVAN and that HIV replication in the kidney is compartmentalized after it occurs.[70–73] Immune complex glomerulonephritis and other forms of medical renal disease, as well as medication-induced renal injury, also can occur in HIV-infected individuals. Biopsy confirmation is recommended when HIVAN is suspected.[65,66,68,74] Progression of HIVAN to renal failure is more commonly seen among those of African ancestry.[74] Before the availability of antiretroviral therapy, HIVAN was strongly associated with increased mortality.[66,68] Antiretroviral therapy appears to be the most effective therapy, but angiotensin-converting enzyme inhibitors are used commonly in children with proteinuria. Corticosteroid therapy is not consistently effective among children with HIVAN, but cyclosporine-induced remission of HIV-associated nephrotic syndrome also has been reported.[65,67,75]

Hematologic Disorders

Anemia, leukopenia, neutropenia, and thrombocytopenia are common manifestations of HIV infection in children. Many cases of normocytic or microcytic anemia are attributable to chronic disease; macrocytic anemia most often is secondary to zidovudine therapy.[2] Other causes of anemia are iron deficiency, hemoglobinopathies, and red blood cell enzyme defects. Infectious diseases resulting in anemia in HIV-infected children include disseminated *Mycobacterium avium* complex infection, cytomegalovirus infection, and chronic parvovirus infection.[76]

The treatment of anemia in HIV-infected patients depends on the etiology. Therapy with recombinant human erythropoietin facilitates continued use of zidovudine if alternative antiretroviral agents cannot be substituted.[2,77] Some patients with chronic parvovirus infection respond to high-dose immune globulin intravenous (IGIV) therapy.[76]

Leukopenia and neutropenia often result from medication-induced bone marrow depression caused by zidovudine, trimethoprim-sulfamethoxazole, ganciclovir, pentamidine, and other medications. Neutropenia also is observed during the course of various chronic and opportunistic infections, including those caused by parvovirus B19 and *Mycobacterium avium* complex. Granulocyte colony-stimulating factor therapy can be helpful in reversing drug- or disease-induced neutropenia and preventing infectious complications.[78]

Thrombocytopenia in HIV-infected children can occur as a result of either underproduction or shortened survival of platelets. Immune-mediated destruction is a common cause of thrombocytopenia, and antiplatelet antibodies are detectable in most patients. Antiretroviral therapy often leads to resolution of thrombocytopenia. Some children can exhibit an initial response to corticosteroid, IGIV therapy, or the use of intravenous anti-D antibody, but improvement often is short-lived and incomplete. Splenectomy may be indicated for the HIV-infected child with severe thrombocytopenia that is refractory to other measures.[79] Rituximab also has been used in chronic, recurrent HIV-associated immune thrombocytopenia.[80]

Dermatologic Conditions

A wide variety of bacterial, fungal, viral, and parasitic infections of the skin occur in children with HIV infection.[81–83] In particular, molluscum contagiosum, scabies, tinea infections, and oropharyngeal candidiasis occur and recur at high frequency and often are severe and refractory to therapy. Prolonged development of vesicular lesions and recurrences of varicella also may occur.[84] HIV-infected children have a higher than expected incidence of noninfectious inflammatory, eczematoid, psoriatic, neoplastic, and drug hypersensitivity skin conditions.[85] Seborrheic dermatitis manifests as erythema and scaling of the face and scalp in HIV-infected infants or of the nasolabial folds, eyebrows, and postauricular areas in older children. Pruritic papular eruption (PPE) is a chronic eruption of papular lesions commonly encountered in children.[81,86] The etiology is uncertain, but PPE may represent a hypersensitivity reaction to insect bites.[83,86] PPE can cause substantial discomfort and is treated with oral antihistamine medications and topical corticosteroids.[83] Cutaneous eruptions occur with a variety of oral and parenteral medications, cotrimoxazole, and nonnucleoside reverse transcriptase inhibitors being the most commonly implicated.[2] Cutaneous Kaposi sarcoma occurs in HIV-infected children internationally but is rarely seen in the US.[45,52]

Prognosis

In general, children with vertically acquired HIV infection have shorter asymptomatic periods and more rapid disease progression than other individuals with HIV infection.[12,87,88] However, many children demonstrate late onset of symptoms and longterm survival.[87,89] Both the age at diagnosis of an AIDS-defining condition and clinical presentation are important determinants of prognosis. In one study in the US conducted before the advent of antiretroviral therapy, the overall median survival time for children with vertically acquired HIV infection was 30 months. Children who demonstrated AIDS in the first year of life had a median survival time of only about 7 months.[12] Even shorter periods of survival are common in resource-poor countries of the world.[88] Presentation during infancy with opportunistic infection (especially PCP) or HIV encephalopathy portends a poor prognosis, whereas slow decline of $CD4^+$ lymphocyte count, late onset of signs and symptoms of HIV infection,[12,21,87] and occurrence of LIP-PLH have been associated with longer survival.[89]

Beyond infancy, $CD4^+$ T-lymphocyte counts and measurements of plasma HIV viral load have strong prognostic value. The HIV Paediatric Prognostic Markers Collaborative Study[90] was a metaanalysis based on data from 3941 children (with 7297 child-years of follow-up) who had received no antiretroviral therapy, or zidovudine alone. In this study, $CD4^+$ lymphocyte percentage and HIV RNA levels were both independently predictive of the risk for clinical progression or death in children older than 12 months. The CD4⁺ lymphocyte percentage was a stronger predictor of risk than HIV RNA concentration (Fig. 111.4).

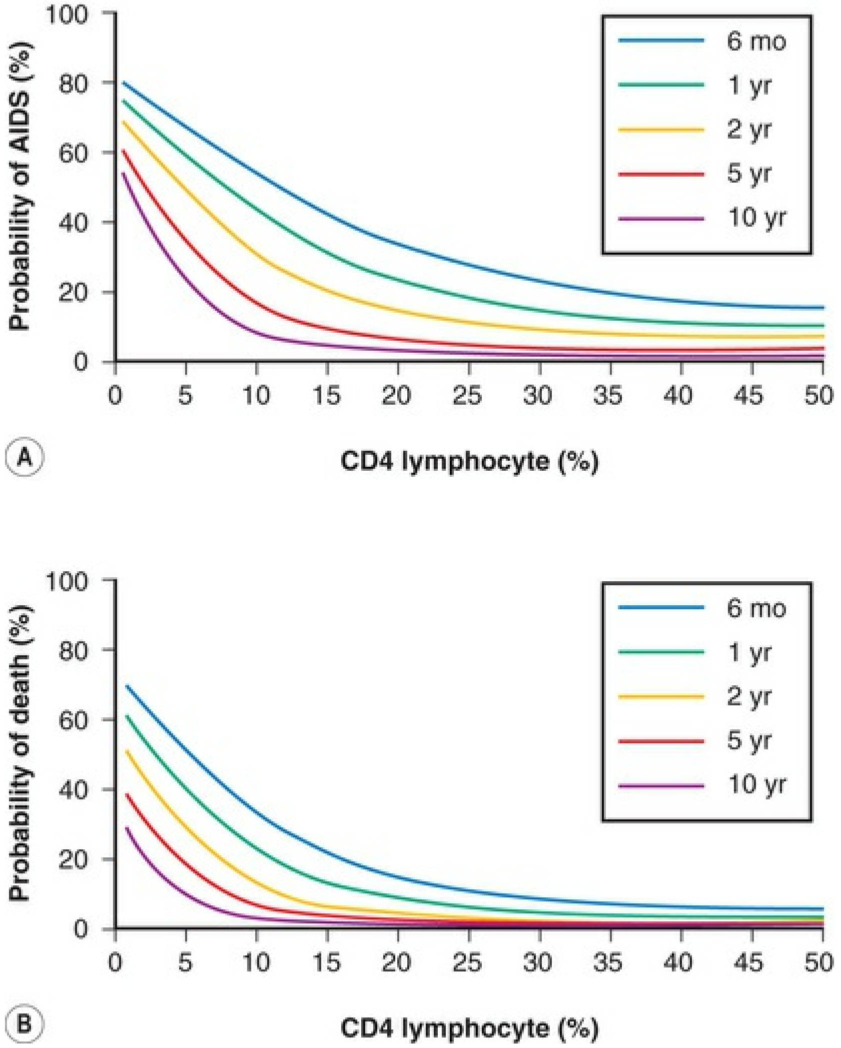

FIGURE 111.4 (A) Estimated probability of AIDS within 12 months by age and CD4 lymphocyte percentage in HIV-infected children receiving no therapy or zidovudine monotherapy. (B) Estimated probability of death within 12 months by age and CD4 lymphocyte percentage in HIV-infected children receiving no therapy or zidovudine monotherapy. (From Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection. https://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf.)

The outlook for children with HIV continues to improve. Combination antiretroviral therapy (cART) is increasingly available throughout the world. It is recommended for all children by the WHO and experts in the US[2,91] because it is able to prevent, ameliorate, or reverse most of the clinical manifestations of HIV infection and reduce morbidity and mortality. Although adherence to antiretroviral medications and tolerance of their side effects remain problematic, the number of pediatric deaths due to HIV/AIDS has been reduced markedly wherever cART has been introduced. Unfortunately, even with cART, the mortality rate for HIV-infected children, adolescents, and young adults remains about 30-fold higher than that for other children in the US.[92] Moreover, opportunistic infections and malignancies may occur for many months after normalization of $CD4^+$ T-lymphocyte counts.[93]

Behaviorally Acquired HIV Infection

In the US and throughout the world, adolescents and young adults are the fastest growing group of HIV-infected individuals. In 2013, youth 13 to 24 years of age represented 21% of all Americans who were newly diagnosed. The youth most often infected were black or Hispanic/Latino; most were young men who have sex with men or who reported injection drug use.[94]

Some of those with behaviorally acquired infection will come to attention with acute retroviral syndrome (fever, sore throat, swollen lymph nodes or tonsils, rash, and other nonspecific symptoms). Acute gastrointestinal complaints (vomiting, diarrhea, oral ulcers) and neurologic findings (including encephalitis, facial nerve palsy, psychosis) also are common with acute retroviral syndrome.[95] Many cases of early HIV infection will be diagnosed after EBV-related mononucleosis was initially suspected.[95] A small fraction (~10%) of new infections will come to medical attention with severe opportunistic infections or AIDS-defining conditions such as cytomegalovirus infections of the gastrointestinal tract.[95] Not all newly diagnosed adolescents are newly infected. Some patients will present with conditions that indicate long established HIV infection and immunologic dysfunction, such as thrush, immune thrombocytopenia, or shingles (varicella-zoster virus). HIV testing should be routinely performed when ostensibly healthy individuals present with these indicator conditions or during evaluation for either sexually transmitted infections or tuberculosis. Some newly diagnosed youth are symptom free at the time of presentation but obtain HIV testing through testing campaigns, partner notification, or provider-initiated testing in their primary care settings.

Clinical care for infected youth includes starting treatment or prophylaxis against opportunistic infections and assessing readiness for antiretroviral treatment. Most youth respond well to antiretroviral therapy.[93,96] Psychological support is critical in caring for those youth who are infected because of behavioral risks, who may have preexisting mental health and substance abuse issues.[96,97] For the newly diagnosed adolescent, care must include a focus on building a therapeutic relationship[98] and on education about HIV diseases and the prevention of transmission of HIV to others.

Infectious Complications of HIV Infection

Allison L. Agwu, Russell B. Van Dyke

Opportunistic infections were central to the identification of the acquired immunodeficiency syndrome (AIDS) and have been a major cause of human immunodeficiency virus (HIV)–associated morbidity and mortality. An unusual clustering of cases of *Pneumocystis jirovecii* (formally *P. carinii*) pneumonia (PCP) in the early 1980s led in part to the recognition of AIDS. Other AIDS-associated opportunistic infections, including disseminated mycobacterial disease, cryptococcal meningitis, cerebral toxoplasmosis, and cytomegalovirus (CMV) retinitis, were recognized soon thereafter.

In the mid-1990s, improved treatment and prevention strategies and the introduction of combination antiretroviral therapy (cART), previously referred to as highly active antiretroviral therapy (HAART), dramatically reduced the incidence of opportunistic infections and the mortality rate for HIV. Between 1994 and 2000, the overall mortality rate for HIV-infected children in the United States decreased from 7.2 to 0.8 deaths per 100 person-years.[1] Likewise, the incidence of most opportunistic infections fell dramatically[2,3] (Table 112.1). Despite these advances, opportunistic infections continue to occur, and physicians must be familiar with the epidemiology and other features of these infections to optimize early identification, prevention, and treatment.[4,5]

TABLE 112.1

Incidence of Infections per 100 Patient-Years Among HIV-Infected Children Before and After the Advent of Combination Antiretroviral Therapy

Condition	Before cART 1986–1998[3,19]	After cART 1997–2014[2,3,5]
OPPORTUNISTIC INFECTIONS		
Pneumocystis jirovecii pneumonia	1.3–5.8	0.09–0.3
Nontuberculous mycobacterial infection	1.3–1.8	0.2–0.15
Cytomegalovirus disease	0.7–1.5	0.03–0.1
Toxoplasmosis	0.06	NA
Progressive multifocal leukoencephalopathy	0.06	NA
Cryptosporidiosis	0.3–0.6	0–0.03
OTHER INFECTIONS		
Otitis media	57	NA
Upper respiratory infection	47	NA
Sinusitis	15	NA
Bloodstream infection	3.3	0.35
Bacterial pneumonia	11.1	1.2–2.1
Bacterial meningitis	0.1	0.05
Varicella	4.7	0.44
Herpes zoster	2.9	0.76–1.1
Candidiasis, esophageal or pulmonary	1.2–1.4	0.04–0.44
Urinary tract infection	1.6	0.35
Tuberculosis	0.4	<0.5

cART, combination antiretroviral therapy; NA, not available.

Increasing numbers of children are being born to HIV-infected mothers. Due to the advances in antiretroviral therapy for the prevention of mother-to-child transmission, most of these HIV-exposed children are HIV-uninfected and do not have the same risk of infections as HIV-infected children.[6] However, HIV-exposed but uninfected children have immunologic abnormalities resulting in an increased susceptibility to childhood illnesses, including diarrhea, pneumonia, and sepsis.[7–11]

Pathogenesis

Healthy neonates are at risk for serious infection because of immaturity of several components of the immune system, including B and T lymphocytes, phagocytes, and complement. The naïvety of the developing immune system is invoked as a possible explanation for susceptibility of the HIV-infected infant or child to rapid HIV disease progression and complicating infections.

HIV infection of the fetus or neonate can have profound effects on cellular immunity. Destruction of the thymus gland is observed in spontaneous abortuses from HIV-infected mothers. Surprisingly, depletion of $CD4^+$ lymphocytes is not recognized at the time of birth. However, as early as 1 or 2 months of age, HIV-infected infants have $CD4^+$ lymphocyte counts significantly lower than those of HIV-exposed but uninfected infants.[12] Suppression of cell-mediated immunity is responsible in large part for the susceptibility of HIV-infected individuals to PCP and opportunistic mycobacterial, fungal, and viral infections.

Despite hypergammaglobulinemia, humoral immune dysfunction occurs in most children with symptomatic HIV infection and predisposes to recurrent bacterial infections. Humoral deficiency results from dysregulation of T-lymphocyte–mediated responses and polyclonal stimulation of B lymphocytes by poorly controlled infectious agents.[13–17] In vitro lymphoproliferative responses to B-lymphocyte mitogens and specific antigens often are poor. In vivo, there is impaired specific antibody production after immunization with T-lymphocyte–independent antigens (e.g., capsular polysaccharide of *Streptococcus pneumoniae*) and T-lymphocyte–dependent antigens, particularly in those not receiving cART or with a low $CD4^+$ count. Primary humoral immune responses and recall responses (i.e., amplification and immunoglobulin class switch) are defective in children with HIV infection.

Phagocytic function can be altered by HIV infection. Neutropenia and defects in neutrophil chemotaxis and bactericidal activity have been described.[18,19] Neutrophil superoxide production can be depressed in children with advanced HIV disease.[20,21] This combination of phagocyte abnormalities compromises the ability of an HIV-infected person to kill bacterial and fungal pathogens. Although the precise pathogenesis of these abnormalities is unknown, studies suggest that neutropenia and neutrophil dysfunction are partly mediated by abnormal regulation by cytokines (e.g., granulocyte colony-stimulating factor [G-CSF]).[22] Recombinant G-CSF administration in HIV-infected adults has reversed neutropenia and corrected neutrophil-killing defects.[23]

Immune Reconstitution Inflammatory Syndrome

Children with advanced immunosuppression who initiate cART often have a rapid improvement in immune competence, reflected by increased $CD4^+$ cell counts. In the setting of an underlying infection, this can result in the appearance or worsening of the infection's symptoms. The infection unrecognized before starting cART can be unmasked by the resulting inflammatory response.

In children, immune reconstitution inflammatory syndrome (IRIS) most often occurs with mycobacterial infections (i.e., *Mycobacterium avium* complex [MAC], *M. tuberculosis,* and the bacille Calmette-Guérin [BCG] vaccine), varicella-zoster virus (VZV), herpes simplex virus (HSV), and cryptococcal infections, but it can be seen with PCP, CMV, hepatitis B and C, toxoplasmosis, and JC virus (i.e., progressive multifocal leukoencephalopathy [PML]).[24,25] IRIS usually occurs within the first 2 to 3 months after initiating cART and is associated with virologic suppression and a rapid rise in the $CD4^+$ lymphocyte count. IRIS should not be interpreted as a failure of cART.

Children should be evaluated carefully for underlying occult infections before initiating cART. The optimal time to start cART in a child with an active opportunistic infection often is not clear and depends on the specific infection. For opportunistic infections without effective therapy (e.g., PML, Kaposi sarcoma), cART should be initiated promptly because immune reconstitution may resolve the infection. For opportunistic infections with effective therapy (e.g., *M. tuberculosis,* MAC, PCP, cryptococcal meningitis), initiating treatment of the opportunistic infection before starting cART may prevent IRIS. The sequencing of opportunistic infection treatment and cART has been studied for several infections and should be reviewed before initiation cART. If symptoms of IRIS develop after cART, the opportunistic infection should be treated, cART usually is continued, and immunomodulating therapy may be considered.

Epidemiology and Etiologic Agents

In children, as in adults, untreated HIV infection is characterized by an increased frequency of a specific group of serious opportunistic and nonopportunistic infections. The increased frequency of common childhood infections of a less serious nature also contributes to the overall morbidity of the disease. The frequency of the various opportunistic infections among HIV-infected children in the years preceding cART varied by age, pathogen, and immunologic status.[26] The most common opportunistic infections among children in the United States included serious bacterial infections (SBIs) such as pneumonia and bloodstream infection (BSI), PCP, nontuberculous mycobacterial infections, and CMV disease (see Table 112.1).[2,3,26] Despite a dramatic decrease in the rate of opportunistic infections among patients receiving cART,[3,27,28] the types of infections that occur are similar.[29,30]

Table 112.1 compares the incidence of infections in children before and after the widespread use of cART. Before cART and the use of PCP prophylaxis in early infancy, 7% to 20% of HIV-infected infants developed PCP, making it the most common AIDS-defining opportunistic infection in children (Table 112.2). More than 50% of cases occurred between 3 and 6 months of age.[31] A low age-adjusted CD4$^+$ lymphocyte count or percentage was the major determinant of risk. Although PCP still is observed in HIV-infected infants and children, the incidence has decreased dramatically in the United States.[3]

TABLE 112.2

Common AIDS-Defining Infections in Children <13 Years of Age Before the Combination Antiretroviral Therapy Era

AIDS-Defining Infection	Proportion of Children (%)
Pneumocystis jirovecii pneumonia	35
Lymphoid interstitial pneumonitis	23
Recurrent bacterial infections	21
Esophageal or pulmonary candidiasis	21
Cytomegalovirus disease	11
Mycobacterium avium complex infection	9
Severe herpes simplex infection	5
Cryptosporidiosis	5

AIDS, acquired immunodeficiency syndrome.

From Centers of Disease Control and Prevention. Personal communication, 2011.

Oral candidiasis occurs in 15% to 40% of children with HIV infection and is more common among children with low CD4$^+$ lymphocyte counts or symptomatic HIV disease.[32,33] Whereas oral candidiasis is common at all stages of HIV disease, esophageal and pulmonary candidiasis are far less common and typically restricted to patients with advanced HIV disease.[4] Esophageal and pulmonary candidiasis accounted for approximately 17% and 4%, respectively, of AIDS-defining illnesses in children before cART.

SBIs (e.g., BSI, pneumonia, sinusitis, meningitis, osteomyelitis, pyogenic arthritis, mastoiditis, abscess of an internal organ) were reported for 40% to 60% of HIV-infected children before cART, with an overall incidence of 44 cases per 100 patient-years of follow-up.[34–36] Recurrent bacterial infections represent an AIDS-defining condition and accounted for 21% of all pediatric AIDS-defining illnesses reported to the Centers for Disease Control and Prevention (CDC) through 2007 (see Table 112.2). Minor infections (e.g., otitis media, urinary tract infection, infections of skin or soft tissue) were threefold more common than serious infections. Use of cART has resulted in a dramatic drop in the incidence of SBIs, but rates remain higher than those for HIV-uninfected children (see Table 112.1).[5]

The incidence of SBIs among HIV-infected children is highest in children younger than 1 year of age who have low CD4$^+$ lymphocyte counts.[37] The Pediatric Spectrum of Disease Project evaluated 21,167 vertically infected children and found 1063 SBIs among 570 children. Sixty-four percent were severely immunocompromised (i.e., CDC immunologic category 3) when the first SBI occurred; 25% had a first infection in the first 6 months of life and 37% by 12 months of age. BSI, pneumonia, and urinary tract infection were the most common.[38]

Streptococcus pneumoniae is the single most common cause of SBIs in HIV-infected children.[34–36,38,39] In a study of HIV-infected children younger than 36 months of age, pneumococcal BSI occurred with an annualized rate of 11.3 episodes per 100 patient-years[40]; this rate is more than threefold that observed for children with sickle cell anemia[41] and 12-fold that reported in one study of adults with AIDS.[42] Other bacteria causing these infections include *Salmonella* species, *Staphylococcus aureus,* and *Neisseria meningitidis*.

Although CMV infection is common, disseminated disease, chorioretinitis, and colitis caused by CMV are uncommon in children.[43] The role of CMV as a cause of pneumonia in HIV-infected children is controversial; CMV usually is associated with another opportunistic pathogen (often *P. jirovecii*). HSV commonly causes infection of the oral or genital mucous membranes that is more severe and prolonged than would be expected[44]; esophageal or pulmonary disease occurs rarely. CMV disease, cryptosporidiosis,[45] and disseminated MAC[46,47] occur predominantly in children with advanced HIV disease and severely depressed $CD4^+$ lymphocyte counts. Without prophylaxis, up to 20% of HIV-infected children with $CD4^+$ lymphocyte counts of less than 50 $cells/mm^3$ develop disseminated MAC infection.

Approach to the HIV-Infected Child With Suspected Systemic or Focal Infection

Fever

Clinical manifestations and diagnostic considerations for HIV-infected children with fever are as diverse as among uninfected children. Fever is a common reason for unscheduled outpatient clinic visits and hospital admissions of HIV-infected children. Although most HIV-infected children with acute febrile illnesses have mild, self-limited illnesses presumably caused by a viral infection, they are at increased risk for more serious illnesses. Differentiation can be difficult (Box 112.1).

Box 112.1

Causes of Fever Without an Obvious Source in HIV-Infected Children

Common causes (e.g., respiratory viruses, urinary tract pathogens)

Bacteremia

Focal bacterial infection (e.g., sinusitis, pneumonia, organ abscess)

Catheter infection

Salmonellosis

Tuberculous or nontuberculous mycobacterial infection

Fungal infection (e.g., candidal esophagitis, cryptococcal meningitis, pneumonia)

Pneumocystis jirovecii infection

Toxoplasmosis

Cytomegalovirus infection

Epstein-Barr virus infection

Herpes simplex virus infection

Hepatitis

Esophagitis

Lymphoma and other types of malignancy

Drug fever

Febrile HIV-infected children require a thorough medical history and physical examination. The character and duration of symptoms, HIV disease status (including the most recent $CD4^+$ lymphocyte count), adherence to cART and opportunistic infection prophylaxis, and history of recent exposures are important. A careful search for evidence of focal infection or inflammation and an assessment of the severity of illness (i.e., toxicity) should be performed. Clinical features of focal infection in HIV-infected children are similar to those observed in immunologically healthy children, with fever and local signs of inflammation often found. BSI should be suspected in an acutely ill child with a serious focal infection such as pneumonia, cellulitis, or osteomyelitis.

The approach to the acutely febrile HIV-infected child without localizing signs can be problematic. Not all patients require diagnostic testing or antibiotic therapy, although both should be considered, especially for those with high fever (>39.4°C) or advanced HIV disease. The likelihood of an opportunistic infection such as disseminated MAC, *Cryptococcus neoformans,* or CMV enteritis or retinitis typically increases as the patient's $CD4^+$ lymphocyte count decreases.

The white blood cell count, often used as a screening test for SBI in immunologically normal children, must be interpreted in the context of the patient's baseline values. Neutropenia commonly results from trimethoprim-sulfamethoxazole (TMP-SMX) use and can result from HIV infection and the use of other medications. Other diagnostic studies can include radiographs of the chest and sinuses; culture of blood for routine bacteria, mycobacteria, and fungi; culture of the urine; culture or testing by molecular methods of throat or nasopharyngeal specimens and blood for viruses (including CMV); cryptococcal and other fungal antigen tests; Epstein-Barr virus serologic tests; hepatic enzyme measurements; and ophthalmologic examination for chorioretinitis. Examination of cerebrospinal fluid (CSF) sometimes is indicated for routine blood cell counts and protein and glucose concentration; bacterial, fungal, and viral polymerase chain reaction (PCR) assays; cryptococcal antigen test; and cytologic tests.

Empiric antibiotic therapy for children who have mild or asymptomatic HIV infection who have an acute febrile illness should be similar to that used in the treatment of immunologically normal children with comparable clinical manifestations. Oral antibiotic therapy is appropriate in most cases. Children with more advanced HIV disease may require agents with broader activity that are administered parenterally.

The selection of antibiotic agents for expectant therapy is influenced by factors such as the likely source of infection (e.g., community-acquired vs. healthcare-associated infection), presence of a central venous catheter, immunization status, use of prophylactic antibiotics, and $CD4^+$ count. Empiric antibiotic therapy should be directed against a limited number of likely pathogens. Unless convincing clinical or laboratory evidence exists for serious opportunistic fungal, mycobacterial, or viral infection, therapy usually is directed against potential bacterial pathogens.

Pneumonia

In the pre-cART era, more than one half of infants with vertically acquired HIV infection initially came to medical attention with lung disease and PCP, bacterial pneumonia, and lymphocytic interstitial pneumonitis (LIP) or pulmonary lymphoid hyperplasia were the most common causes.[48] The likelihood of an opportunistic infection increases as the patient's CD4$^+$ lymphocyte count decreases. With cART and appropriate prophylaxis, PCP and LIP have become rare in the United States, and the incidence of pneumonia overall continues to fall.[5]

The predominant bacterial causes of pneumonia include *S. pneumoniae, S. aureus, M. tuberculosis,* and occasionally gram-negative organisms. The rate of tuberculosis is increased among HIV-infected children and adults, and unlike other opportunistic infections, the CD4$^+$ lymphocyte count is not a good indicator of tuberculosis risk. Other infectious causes of pneumonia include community-acquired respiratory viruses, CMV, HSV, and fungi (e.g., *Candida, Cryptococcus neoformans, Histoplasma capsulatum*).

The clinical manifestations of bacterial pneumonia are similar to those seen in immunologically normal children. The usual manifestations of PCP include acute onset of fever, cough, tachypnea, hypoxia, and respiratory distress. However, PCP also can progress in a slow and insidious manner. Decreased breath sounds and hypoxia can occur, but crackles are uncommon. LIP usually is insidious and slowly progressive. Patients can have cough and wheezing. Associated findings include generalized lymphadenopathy, hepatosplenomegaly, parotid enlargement, and digital clubbing.

Radiographic features of pneumonia in HIV-infected children usually are not distinctive. Bacterial pneumonia can be associated with focal or diffuse infiltrates. The typical radiographic picture of PCP is diffuse, reticular interstitial and alveolar infiltrates that are most prominent in the perihilar areas (Fig. 112.1). Air bronchograms, focal infiltrates, pneumatoceles, or pneumothorax can occur in some cases. The chest radiograph can be normal at the time of presentation. The radiographic features of tuberculosis can be similar to those of HIV-uninfected children, although atypical findings, such as multilobar infiltrates and diffuse interstitial disease, can occur in HIV-infected children.[49] The typical radiographic features of LIP include diffuse, reticulonodular densities and hilar adenopathy (Fig. 112.2).

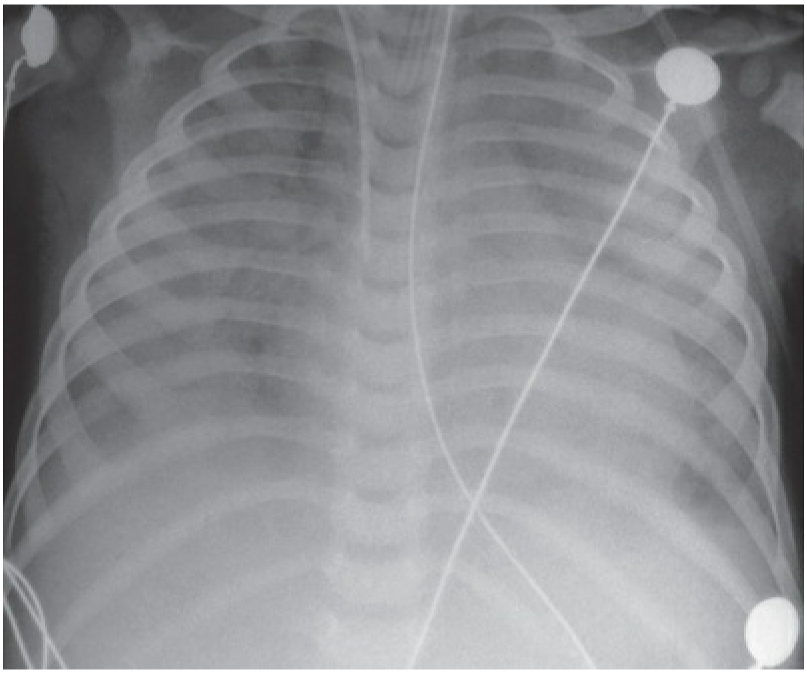

FIGURE 112.1 Chest radiograph shows *Pneumocystis jirovecii* pneumonia in a 2-year-old boy with vertically acquired human immunodeficiency virus infection. The interstitial lung disease is bilateral.

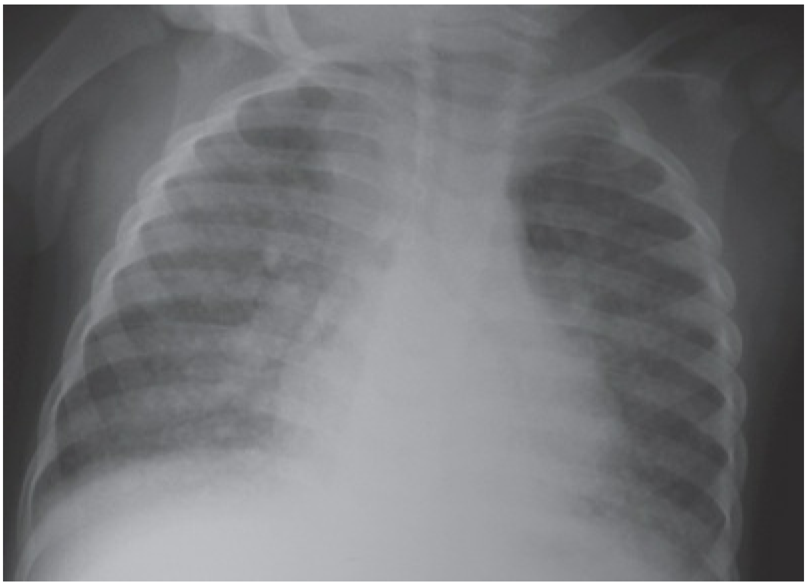

FIGURE 112.2 Typical lymphocytic interstitial pneumonitis or pulmonary lymphoid hyperplasia is the presenting feature of vertically acquired human immunodeficiency virus infection in a 23-month-old

infant with slowly worsening bronchiolitis and hypoxia. Fungal, bacterial, and other viral causes were excluded. Plain radiograph shows diffuse reticulonodular infiltration and perihilar adenopathy. There was complete resolution 4 months after starting combination antiretroviral therapy. (Courtesy E.N. Faerber, J. Chen, and J. Foster, St. Christopher's Hospital for Children, Philadelphia, PA.)

A complete blood cell count, measure of oxygen saturation, and blood cultures should be obtained. A tuberculin skin test (TST) or an interferon γ release assay (IGRA) should be performed for every appropriate-age, HIV-infected child with pneumonia. A negative TST result (i.e., induration of ≤5 mm) or IGRA result does not exclude tuberculosis. Most children with a normal (or unchanged from previous) chest radiograph and normal arterial oxygen saturation value have self-limited (presumably viral) illness. A nasopharyngeal specimen for rapid diagnostic tests (e.g., fluorescent antibody test, enzyme immunoassay), nucleic acid testing, or culture for viruses may be helpful.

Positive results for the blood culture or evidence of a segmental or lobar infiltrate suggests bacterial pneumonia. PCP is likely in a child with a low CD4$^+$ lymphocyte count, the acute onset of respiratory distress, typical reticular interstitial infiltrates, and hypoxemia. Marked elevation of the serum lactate dehydrogenase concentration (>1000 IU/L) supports a diagnosis of PCP. Bronchoalveolar lavage is indicated for confirmation of suspected PCP and exclusion of other opportunistic infections in children with advanced HIV disease. If tuberculosis is strongly suspected for a child with a pulmonary infiltrate and negative TST results, gastric or bronchoalveolar lavage is warranted.

Atypical features of pneumonia may necessitate bronchoscopy or open-lung biopsy for histology, molecular testing, and cultures to evaluate the wide array of diagnostic possibilities. A presumptive diagnosis of LIP can be made on the basis of characteristic clinical features and radiographic changes persisting for more than 2 months in the absence of another explanation, particularly in a child with newly diagnosed HIV disease.

Empiric antibiotic therapy is indicated for children with characteristic features of bacterial pneumonia. A β-lactum agent, with or without a β-lactamase inhibitor, or a third-generation cephalosporin is appropriate for children with normal CD4$^+$ lymphocyte counts. Including treatment of *Mycoplasma* is appropriate for school-aged children. Coverage for methicillin-resistant *S. aureus* (MRSA) is appropriate for children with severe disease or profoundly depressed CD4$^+$ lymphocyte counts.

Treatment of tuberculosis in HIV-infected children is complex because there are multiple drug interactions between antiretroviral drugs, other prophylactic agents such as the macrolides and azoles, and antimycobacterial drugs. Guidelines should be consulted and advice obtained from an expert in the treatment of the two diseases.[4] Tuberculosis treatment should be started immediately, and the child's antiretroviral therapy should be altered as necessary. Directly observed therapy is essential. Specific considerations include the importance of rifampin in tuberculosis therapy and its potent induction of the hepatic CYP3A enzyme system that precludes the use of all protease inhibitors. Rifabutin should be substituted with appropriate dosage adjustments, or cART should not include a protease inhibitor.

Central Nervous System Infections

Except for children with advanced HIV disease, the causative agents, clinical manifestations, and CSF findings of meningitis and encephalitis are similar to those observed in immunocompetent hosts. *C. neoformans* and JC virus are two opportunistic pathogens that can cause central nervous system (CNS) infection in HIV-infected children. *C. neoformans* is a common cause of meningitis in patients with advanced HIV disease and severely depressed CD4$^+$ lymphocyte counts. Cryptococcal meningitis often is characterized by an indolent course of illness. Complaints of fever, intermittent headache, and vomiting are common. Signs of meningeal inflammation can be absent. Rarely, cryptococcal CNS infection can cause acute focal neurologic signs and symptoms.[50,51] The CSF cell count and the glucose and protein values can be normal. Important CSF diagnostic studies include an India ink stain, cryptococcal antigen testing, and culture.

JC virus is a polyomavirus that causes progressive multifocal leukoencephalopathy (PML) in people with advanced immunosuppression. PML is a progressive, demyelinating disease of the CNS, characterized by focal neurologic abnormalities (e.g., visual deficits, motor weakness), personality and cognitive changes, confusion, ataxia, and seizures. Neuroimaging reveals focal white matter lesions without a mass effect (Fig. 112.3). Most cases of PML occur in patients with advanced HIV disease. PML was uncommon in HIV-infected children before cART and has become rare.[3,26]

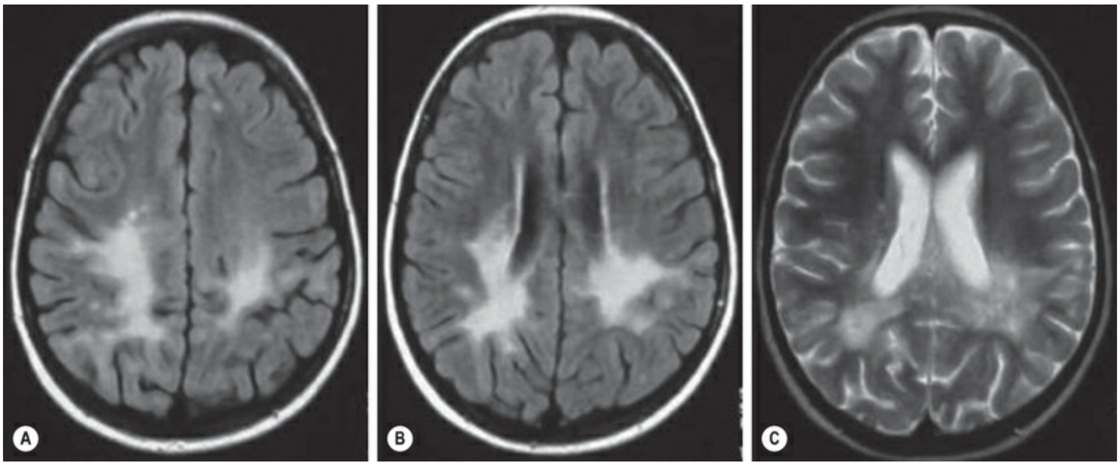

FIGURE 112.3 Progressive multifocal leukoencephalopathy. A 12-year-old boy, who recently immigrated from Zambia and was newly diagnosed with acquired immunodeficiency syndrome, had a 2- to 3-year history of severe headache and diarrhea. Magnetic resonance imaging (MRI) showed predominantly right-sided white matter lesions. Antimicrobials and combination antiretroviral therapy (cART) were begun; 9 weeks after starting cART, the human immunodeficiency virus viral load was low, but he was subdued and tearful, and had decreased strength and reflexes on the left side. Imaging showed progression of previous abnormalities. Cerebrospinal fluid (CSF) appeared normal, but the CSF polymerase chain reaction result was positive for JC virus. The fluid-attenuated inversion recovery (FLAIR) (A and B) and T2-weighted MRI (C) scans show increased signal within the periventricular white matter tracts extending outward to the subcortical areas, involving the parietal lobes, both hemispheres, corpus callosum, and brainstem, with no mass effect. (Courtesy A.R. Feingold and D. Meislich, Cooper University Hospital, Camden, NJ.)

The usual clinical course of PML is inexorable deterioration of

CNS function, leading to death within a few months of diagnosis. The mainstay of therapy is to optimize antiretroviral therapy because an improved immune status can produce clinical improvement. Antiviral agents directed against JC virus, including cytosine arabinoside and cidofovir, have no demonstrated efficacy.

Cerebral toxoplasmosis occurs in patients with advanced HIV disease and severely depressed $CD4^+$ lymphocyte counts. Presenting features include fever, headache, seizures, focal neurologic abnormalities, and altered consciousness. Computed tomography or magnetic resonance imaging of the brain typically reveals multiple ring-enhancing lesions with surrounding edema. Toxoplasmosis almost invariably represents reactivation of prior infection. Patients who are seronegative for *Toxoplasma* are unlikely to have cerebral toxoplasmosis, and it is useful to periodically document the serologic status of HIV-infected children.

The differential diagnosis of CNS toxoplasmosis includes bacterial and fungal infections and CNS lymphoma. Brain biopsy, the definitive diagnostic procedure, usually is reserved for patients who fail to respond clinically and radiographically to empiric therapy for toxoplasmosis. Risk factors for toxoplasmosis include direct and indirect contact with cats (e.g., litter boxes) and consumption of undercooked meats. Families should be counseled about the risk.

CNS mass lesions in children with HIV infection pose special diagnostic considerations. Definitive diagnosis may require tissue examination. Infectious causes include bacterial brain abscess, toxoplasmosis, cryptococcoma, and tuberculoma. Noninfectious causes such as lymphoma also should be considered.

Diarrhea

As for uninfected children, episodes of diarrhea in HIV-infected children are often acute and self-limited, with no apparent long-term effects. Persistent or recurrent diarrhea, however, can adversely affect quality of life and place the child at risk for malnutrition and further immunologic impairment.

Gastroenteritis can be caused by any of the usual enteric pathogens, including rotavirus, *Salmonella, Shigella,* enterotoxigenic *Escherichia coli, Campylobacter, Vibrio cholera, Clostridium difficile,* *Entamoeba histolytica,* enteric adenoviruses, and *Giardia intestinalis,* irrespective of the child's $CD4^+$ count. Opportunistic pathogens, such as CMV, MAC, *Cryptosporidium,* microsporidia, and *Cystoisospora (Isospora)*, usually occur with advanced immunosuppression. The diagnostic evaluation should be guided by the patient's $CD4^+$ count and clinical presentation.

Many episodes of acute enteritis do not require diagnostic evaluation. However, if gastrointestinal symptoms are severe or persistent, several investigations should be considered. Examination of the stool for rotavirus (i.e., antigen or nucleic acid test) and for ova and parasites (i.e., routine and acid-fast staining) for detection of *Cryptosporidium* and *Cystoisospora* spp. should be considered. Stool cultures for bacterial enteric pathogens are obtained if the child has fever. Blood culture is obtained to exclude *Salmonella* bacteremia. Studies for *C. difficile* are performed if there is a history of recent antibiotic use. Documentation of active CMV replication by blood antigenemia, nucleic acid testing, or culture can be helpful. Stool cultures for CMV and MAC typically are not useful.

Upper endoscopy is reserved for patients with persistent diarrhea of unknown cause. Colonoscopy should be considered in patients with dysentery without an identified pathogen. Biopsies are obtained for evaluation of bowel histology and detection of *Giardia,* CMV, *Cryptosporidium,* and MAC.

Management must include close attention to nutritional support. Empiric antibiotic therapy for *Salmonella* spp. should be considered for the child with dysentery and signs of toxicity. Other therapeutic interventions are guided by results of diagnostic studies. Treatment guidelines are available for the management of specific opportunistic infections causing diarrhea.[4] Some of the antiretroviral agents can cause diarrhea and always should be considered, particularly if no infectious cause is identified.

Esophagitis

Esophagitis is common among people with AIDS. Symptoms include irritability, pain in the esophagus or chest, difficulty swallowing, hiccups, and fever. Esophagitis can have infectious and noninfectious causes. *Candida* species are the most common infectious cause. Children with esophageal candidiasis do not always have concomitant oral candidiasis. Viral causes of esophagitis include CMV and HSV.[52] Esophageal disease caused by bacteria (including mycobacteria) is uncommon. Other causes of esophageal disease in HIV-infected children include lymphoma, acid reflux, and aphthous ulcers.

Empiric antifungal therapy is given when oral candidiasis and typical clinical features of esophagitis are identified. Barium esophagography or endoscopy is considered if the presentation is atypical or the patient fails to improve within 5 to 7 days. Radiographic differentiation of various types of esophageal ulcerative disease (e.g., candidiasis vs. CMV disease) and recognition of dual infection are impossible. If ulcerative or nodular lesions are identified radiographically, esophagoscopy and biopsy should be performed.

Oral Infections

Candidiasis is the most common oral infection in HIV-infected children.[44] Several clinical variants are recognized, including pseudomembranous, hyperplastic, and erythematous candidiasis and angular cheilitis. Although oral candidiasis may respond to oral nystatin or clotrimazole, oral fluconazole is more effective.

Oral ulcers are common in HIV-infected children. CMV and HSV are common infectious causes. Three types of aphthous ulcers occur frequently: aphthous major (i.e., large ulcers persisting >3 weeks), aphthous minor (i.e., smaller ulcers that heal spontaneously within 5–10 days), and aphthous herpetiformis (i.e., multiple, discrete ulcers resembling those caused by HSV). Aphthous major is the most common form observed in HIV-infected patients; concomitant pharyngeal and esophageal ulcers occur in some cases.

Diagnostic evaluation and management of children with oral ulcers are based on clinical presentation. A surface culture for HSV and empiric therapy with acyclovir may suffice for patients with lesions typical of herpetic stomatitis. Biopsy and cultures for viruses, mycobacteria, and fungi should be considered if initial diagnostic studies are negative, the ulcers are large or deep, or the ulcers fail to heal in an appropriate length of time with or without empiric therapy.

Prevention of Infection

Guidelines for the prevention and treatment of opportunistic infections in HIV-infected and HIV-exposed children and HIV-infected adolescents and adults are published by the US Public Health Service and are updated regularly.[4] Guidelines for vaccination of the immunocompromised host were published from the Infectious Diseases Society of America in 2014.[53]

Routine Immunization

A modified immunization schedule for HIV-infected children and HIV-exposed infants with undefined HIV infection status is available and should be consulted.[4] Children immunized before cART usually have poor vaccine responses associated with a low $CD4^+$ count and high viral load at the time of immunization. With immune reconstitution after cART, the response to immunization is much improved, although protective immunity can wane over time.[54] Although it is likely that children with immune reconstitution after severe immunosuppression can benefit from reimmunization, data are not readily available to support reimmunization with most vaccines. However, some data demonstrate low antibody titers to measles, mumps, and rubella in children immunized before cART, and reimmunization is recommended. Reimmunization may be considered for children at increased risk of exposure to vaccine-preventable diseases (e.g., child traveling to an endemic region who was initially vaccinated at a low $CD4^+$ count).

The bacterial vaccines (i.e., diphtheria, tetanus, pertussis, *H. influenzae* type b, and pneumococcus) should be administered to all HIV-infected children according to the routine childhood schedule.[4,55] Because HIV-infected people are at increased risk of meningococcal C, W, and Y infection related directly to viral load and inversely to $CD4^+$ count, the MenACWY conjugate vaccine is recommended beginning at 2 months of age, with catch-up inoculations for older children and repeated booster doses.[56] HIV-infected children should receive pneumococcal immunization as recommended in the modified immunization schedule.[4,55] Key points include the following:

- HIV-exposed and infected infants and children between the ages of 2 and 59 months should receive the 13-valent pneumococcal vaccine (PCV13) on the same schedule as that recommended for healthy infants and children, including series completion with PCV13 for those who initiated immunization with PCV7.
- A single dose of PCV13 should be administered routinely to HIV-infected children between 6 and 18 years who did not receive PCV13 before 6 years of age.
- HIV-infected children 2 years of age or older should receive the 23-valent pneumococcal polysaccharide vaccine (PPSV23) at least 8 months after their last PCV dose, with a single revaccination with PPSV23 5 years later.
- If not previously vaccinated with PPSV23, children and adolescents between 6 and 18 years of age should receive 1 dose of PPSV23.
- HIV-infected children 2 months of age and older should receive meningococcal ACWY conjugate vaccination, with booster doses as necessary for other children at high risk of infection.[55]

Beginning at 12 months of age, two doses of the live attenuated measles, mumps, and rubella (MMR) vaccine and varicella (V) vaccine should be administered to HIV-infected children, except those who are severely immunosuppressed (i.e., CDC immunologic category 3 and $CD4^+$ lymphocytes <15%), who are at risk for dissemination of the vaccine virus.[4] The quadrivalent measles-mumps-rubella-varicella (MMRV) vaccine should not be administered to HIV-infected children because immunogenicity and efficacy data for MMRV are lacking. Reimmunization with two additional doses of the MMR vaccine is recommended for children who were immunized before starting cART unless immunity has been demonstrated serologically.[57,58] Use of the rotavirus vaccine in HIV-infected children should be considered in accordance with guidelines.[4] Inactivated viral vaccines (i.e., hepatitis A, hepatitis B, poliovirus, and human papillomavirus) should be administered to all HIV-infected children according to the routine childhood immunization schedule. Inactivated influenza immunization is recommended annually for all HIV-infected children beginning at 6 months of age. It is important to immunize family members and other close contacts.

Passive Immunization

Varicella immune globulin (see Chapter 205) should be administered as early as possible after exposure of a susceptible HIV-infected child to an individual with chickenpox or zoster.[4]

The beneficial effects of immune globulin intravenous (IGIV) for HIV-infected children was demonstrated in the pre-cART era.[36,59] However, cART and the widespread use of TMP-SMX prophylaxis have limited the value of IGIV. Current guidelines limit its use to HIV-infected children with hypogammaglobulinemia (i.e., immunoglobulin G <400 mg/dL) or with recurrent bacterial infections despite appropriate immunization and antibiotic prophylaxis.[4]

Pneumocystis jirovecii Pneumonia Prophylaxis

Identification of children at risk for PCP is complicated by two factors. First, HIV-infected infants, who are at greatest risk for PCP, may not be known to be at risk for HIV infection (i.e., mother is not known to be HIV infected) or may be known to be at risk but not have a confirmed infection. Second, because normal $CD4^+$ lymphocyte counts are age specific, a single $CD4^+$ lymphocyte threshold cannot be used for defining the risk of PCP in all children. Guidelines for primary prophylaxis against PCP published by the CDC take these issues into account.[4] All HIV-infected infants should receive PCP prophylaxis until they are 12 months of age, at which time the need for prophylaxis is determined by age-specific $CD4^+$ lymphocyte values. HIV-infected children 12 months of age or older who meet criteria for CDC immunologic category 3 should receive prophylaxis. All HIV-exposed infants should be started on PCP prophylaxis at 4 to 6 weeks of age unless demonstrated to be uninfected or presumptively uninfected (Box 112.2). Infants with indeterminate infection status should receive prophylaxis until shown to be uninfected or presumptively uninfected. Children 12 months of age or older who experience immune reconstitution after cART can have primary prophylaxis stopped safely if they have received more than 6 months of cART and have $CD4^+$ cell counts exceeding CDC immunologic category 3 for more than 3 consecutive months. Children who have had an episode of PCP should receive secondary prophylaxis to prevent recurrence. Most children can have secondary prophylaxis safely stopped if they meet the criteria for stopping primary prophylaxis.

Box 112.2

Classification of HIV Infection Status of Children Born to HIV-Infected Mothers

Definitive Infection

- Positive virologic results on two separate specimens at any age, *or*
- Age >18 months plus a positive virologic test or a positive confirmed HIV-antibody test[a]

Presumptive Exclusion of Infection in a Nonbreastfed Infant

- No clinical or laboratory evidence of HIV infection, two negative virologic tests, both obtained at ≥14 days of age and one obtained at ≥4 weeks of age plus no positive virologic tests, *or*
- One negative virologic test at ≥8 weeks of age plus no positive virologic test, *or*
- One negative HIV antibody test at ≥6 months of age plus no positive virologic test

Definitive Exclusion of Infection in a Nonbreastfed Infant

- No clinical or laboratory evidence of HIV infection plus two negative virologic tests, both obtained at ≥1 month of age and one obtained at ≥4 months of age, plus no positive virologic tests, *or*
- Two or more negative HIV antibody tests at ≥6 months of age

---

Guidelines for the prevention and treatment of opportunistic infections among HIV-exposed and HIV-infected children: recommendations from CDC, the National Institutes of Health, the HIV Medicine Association of the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the American Academy of Pediatrics. MMWR Recomm Rep 2009;58(RR-11):1–166.

TMP-SMX is the drug of choice for PCP prophylaxis. It is given orally at 5 to 10 mg/kg of TMP component per day (maximum of 320 mg) in 2 divided doses on 3 consecutive days per week.[4] Alternative oral dosing schedules include a single dose on 3 consecutive days per week or 2 divided daily doses. TMP-SMX also is effective in preventing toxoplasmosis and some bacterial infections. Alternative regimens for children who are intolerant of TMP-SMX include oral dapsone, oral atovaquone, and aerosolized pentamidine.[4]

Mycobacterial Infection

An annual TST or IGRA, depending on age, is recommended for all HIV-infected children to diagnose latent mycobacterial infection. The use of control skin testing to identify anergy is not recommended. When identified, treatment for latent tuberculosis should be instituted.

Clinical trials have demonstrated the effectiveness of clarithromycin and azithromycin as primary prophylaxis for MAC infection.[60,61] Although rifabutin also is effective for the prevention of MAC infection, rifabutin should be used as an alternative agent for patients who are unable to tolerate macrolides. Current guidelines recommend that HIV-infected adults and adolescents receive prophylaxis if their $CD4^+$ lymphocyte count is less than 50 cells/mm^3. Recommendations for starting MAC prophylaxis in children are based on the child's age and $CD4^+$ lymphocyte count: ≥6 years of age, <50 cells/mm^3; 2 to 6 years of age, <75 cells/mm^3; 1 to 2 years of age, <500 cells/mm^3; and <12 months, <750 cells/mm^3. The pediatric dose is 7.5 mg of clarithromycin/kg/dose (maximum, 500 mg) orally twice each day or 20 mg of azithromycin/kg/dose (maximum, 1200 mg) orally once weekly.

Fungal Infections

Several trials of prophylaxis against *Candida* infections in adults receiving daily or weekly fluconazole indicate that clinical relapses can be prevented. Emergence of resistance to fluconazole, particularly among species of *Candida* other than *C. albicans*, is a concern.[62,63] Primary prophylaxis of candidiasis in HIV-infected infants and children is not recommended.[4] For children with infrequent recurrences, it is reasonable to treat each clinical episode. Children with frequent recurrences or a history of esophageal candidiasis are candidates for prophylaxis with oral fluconazole.

Specific circumstances dictate the use of antifungal agents for prophylaxis of systemic noncandidal fungal infections in HIV-infected patients.[4] Prospective, controlled trials indicate that fluconazole and itraconazole are effective in the prevention of cryptococcosis in adults with advanced HIV disease (CD4$^+$ lymphocyte count <50 cells/mm^3).[4] Primary prophylaxis for cryptococcosis usually is not appropriate for children. Secondary prophylaxis is administered if a child has had cryptococcosis. Although secondary prophylaxis has not been studied for children and decisions should be made for each case, secondary prophylaxis usually can be discontinued in children 6 years of age or older after 1 year and when they have had a CD4$^+$ count of ≥100 cells/mm^3 and a suppressed viral load while on cART for at least 3 months.[4]

Prognosis

Opportunistic infections and nonopportunistic infections are important clinical indicators of HIV disease progression, immunologic deterioration, and early death. PCP, especially when it occurs during the first year of life, portends a poor prognosis for long-term survival in the absence of cART.[64,65] In one study, children with recurrent bacterial infections or LIP had at least a fourfold longer survival time than those with PCP, disseminated MAC disease, CMV infection, tumors, or PML.[64]

Administration of cART has resulted in a marked reduction in the progression to AIDS, opportunistic infections, and hospitalizations and provided improved survival.[1,66–68] However, the mortality rate for HIV-infected children and youth remains 30 times that for healthy children. Many of these deaths are caused by opportunistic infections, resulting from virologic failure due to poor adherence and viral resistance.[5] As HIV has become a chronic condition, there are concerns about long-term toxicities resulting from HIV and its treatment, including cardiovascular, metabolic, neurologic, and other end-organ disease.[5]

Management of HIV Infection

George Kelly Siberry

The treatment and prognosis of pediatric human immunodeficiency virus (HIV) infection have changed dramatically since the start of the epidemic in the 1980s. The Department of Health and Human Services (DHHS) Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children has developed guidelines for use of antiretroviral agents in pediatric HIV infection.[1] These guidelines are updated regularly to ensure that recommendations are based on the most recent evidence. Similarly, specialists in pediatric HIV infection periodically update guidelines for the prevention and treatment of opportunistic infections (OIs) in HIV-infected and HIV-exposed, uninfected children.[2] This chapter emphasizes the predominantly outpatient care-based approach to use of antiretroviral therapy (ART).

Antiretroviral Therapy

The terms *highly active ART* (HAART) and *combination ART* (cART) have been used to distinguish the potent, multidrug ART regimen that is the current standard of care from single-drug, two-drug, and other less potent drug regimens used early in the HIV epidemic. In this chapter, the term ART will be used, instead of HAART or cART, to describe the multidrug regimens in current use.

Therapeutic Agents

As of 2015, more than 20 antiretroviral drugs (ARVs) are available for use in HIV-infected adults and adolescents, most of which have an approved pediatric treatment indication and are available as a pediatric formulation or in capsule size (Table 113.1). The therapeutic efficacy of these agents results from interruption of viral replication via several mechanisms (Fig. 113.1):

TABLE 113.1

Antiretroviral Drug Formulations and Pediatric Approval Status (as of June 2015)

Name (Abbreviation)	Formulations	Pediatric Approval (Age)
NUCLEOSIDE/NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS		
Abacavir (ABC)	Solution, tablet	>3 mo
Didanosine (ddI)	Powder for solution, tablet for suspension, capsule	>2 wk
Emtricitabine (FTC)	Solution, capsule	All ages
Lamivudine (3TC)	Solution, tablet	All ages
Stavudine (d4T)	Solution, capsule	All ages
Tenofovir disoproxil fumarate (TDF)	Powder (for mixing with food), tablet	≥2 yr
Zidovudine (ZDV)	Syrup, capsule, tablet	All ages, including premature infants
NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS		
Efavirenz (EFV)	Capsule, tablet	≥3 kg and ≥3 mo
Etravirine (ETR)	Dispersible tablet	≥6 yr
Nevirapine (NVP)	Suspension, tablet (immediate-release and extended release)	≥15 days[a]
Rilpivirine (RPV)	Tablet	No
PROTEASE INHIBITORS		
Atazanavir (ATV)	Powder, capsule	>3 mo and ≥10 kg
Darunavir (DRV)	Suspension, tablet	≥3 yr
Fosamprenavir (FPV)	Suspension, tablet	≥4 wk
Indinavir (IDV)	Capsule	No
Lopinavir/ritonavir (LPV/r)	Solution, tablet	≥14 days
Nelfinavir (NFV)	Tablet (dissolvable)	≥2 yr
Saquinavir (SQV)	Capsule, tablet	No
Tipranavir (TPV)	Solution, capsule	≥2 yr
ENTRY INHIBITORS		
Enfuvirtide (T-20)	Injection	≥6 yr
Maraviroc (MVC)	Tablet	≥2 yr
INTEGRASE STRAND TRANSFER INHIBITORS		
Dolutegravir (DTG)	Tablet	≥30 kg and ≥6 yr
Elvitegravir (EVG)	Tablet	No
Raltegravir (RAL)	Tablets	≥4 wk
PHARMACOLOGIC ENHANCERS		
Ritonavir (RTV)	Solution, capsule, tablet	—[b]
Cobicistat (COBI)	Tablet	No

[a] Approved for infants <14 days of age as prophylaxis against maternal–child transmission.

[b] RTV is approved for and but is no longer used as an antiretroviral agent in children as young as 4 wk. As a pharmacokinetic enhancer in coformulated LPV/r, it is approved for those ≥14 days of age.

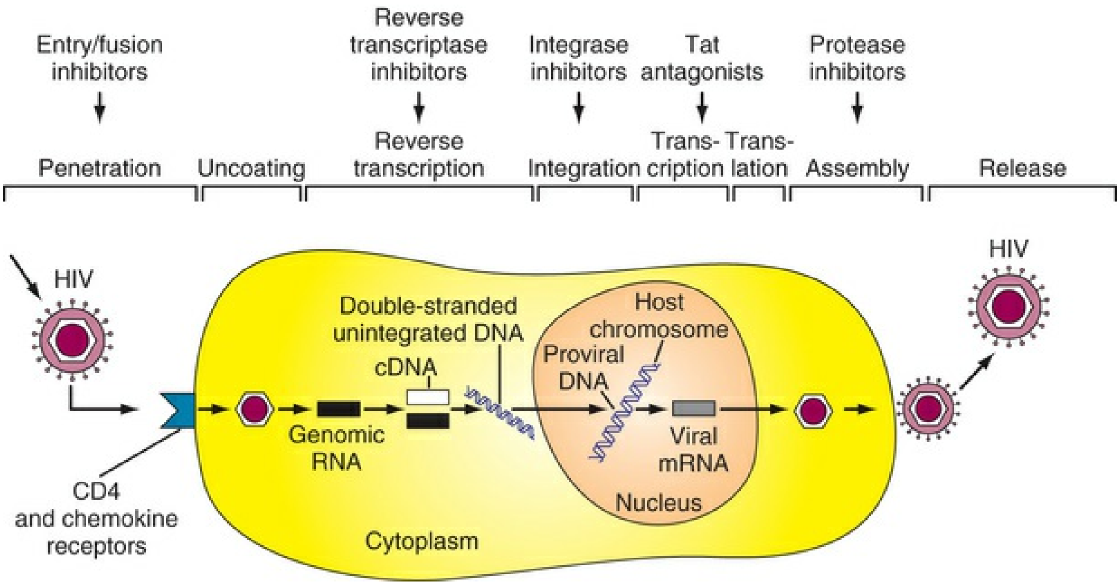

FIGURE 113.1 Human immunodeficiency virus (HIV) life cycle and location of action of various antiretroviral medications. cDNA, complementary DNA; mRNA, messenger RNA.

- Prevention of viral entry: C-C chemokine receptor type (CCR5) antagonists and fusion inhibitors
- Blockade of the early stage of viral replication: nucleoside/nucleotide analogue reverse transcriptase inhibitors (NRTIs/NtRTIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs)
- Inhibition of integrase-mediated strand transfer, which is necessary for integration of the viral genome: integrase strand transfer inhibitors (INSTI) or, simply, integrase inhibitors
- Interference with cleavage of HIV proteins by the viral protease: protease inhibitors (PIs)

Nucleoside and Nucleotide Analogue Reverse Transcriptase Inhibitors

The NRTIs were the first class of ARVs available for the treatment of HIV infection. NRTIs inhibit the HIV reverse transcriptase enzyme, which is responsible for the reverse transcription of viral RNA into DNA. Like the NRTIs, the NtRTI tenofovir competitively inhibits viral reverse transcriptase, but because it already possesses a phosphate molecule, it bypasses the initial phosphorylation step that is required for activation of NRTIs.

NRTIs/NtRTIs are the backbone of ART. In general, two of these agents are used with a PI, NNRTI, or INSTI as first-line therapy. Fixed-dose combinations of NRTIs/NtRTIs are available to simplify dosing. With subsequent regimens, one or more of the NRTIs used in an earlier regimen are often used again to take advantage of a favorable resistance profile.[3]

NRTIs/NtRTIs inhibit the synthesis of mitochondrial DNA (mtDNA), leading to depletion of mtDNA and impaired mitochondrial function. This effect contributes to the toxicities associated with NRTIs/NtRTIs, such as peripheral neuropathy, pancreatitis, and myopathy. Unusual but serious toxicities that can occur with use of NRTIs/NtRTIs include lactic acidosis, hepatic steatosis, cardiomyopathy, and rapidly ascending muscular weakness. The order of potency of the NRTIs/NtRTIs in inhibiting mtDNA synthesis in vitro is didanosine (ddI) > stavudine (d4T) > zidovudine (ZDV) > lamivudine (3TC), abacavir (ABC), and tenofovir.[4] ddI and d4T are not used as first-line agents because of these toxicities. Tenofovir appears to cause fewer mitochondrial toxicities, but concerns about its deleterious effects on bone and kidneys limit its use in children; studies in adults suggest that tenofovir alafenamide (TAF), a different oral form of tenofovir, can achieve therapeutic activity with less risk of bone and kidney toxicity than the oral form, tenofovir disoproxil fumarate (TDF).[5]

Non-Nucleoside Analogue Reverse Transcriptase Inhibitors

The NNRTIs have specific activity against HIV-1 but not HIV-2 or other retroviruses. They noncompetitively bind to and disrupt the catalytic site of reverse transcriptase. Because drug resistance to NNRTIs requires a single mutation that does not appear to affect viral fitness, resistance can develop rapidly after initiation of NNRTI as part of a nonsuppressive regimen. Cross-resistance readily occurs between the NNRTIs efavirenz (EFV), nevirapine (NVP), and rilpivirine (RPV); cross-resistance is less common with etravirine (ETR). NNRTI-based ART regimens are at least as effective as PI-based regimens in achieving durable viral suppression. In addition, NNRTIs appear to be associated with less long-term toxicity than PIs.[1]

NNRTIs are associated with several types of hepatic toxicity, including asymptomatic elevation in transaminases, clinical hepatitis, and hypersensitivity reactions with hepatitis. In HIV-infected adults, risk factors for hepatic toxicity with NVP include elevated baseline serum transaminases, hepatitis B virus (HBV) or hepatitis C virus (HCV) infection, female gender, and higher CD4$^+$ lymphocyte counts (CD4 counts). However, serious liver dysfunction appears to occur much less commonly in children receiving NVP than in adults.[6]

Hypersensitivity reactions are reported more commonly with NNRTIs (especially NVP) than with other antiretroviral agents. Effects of EFV on the central nervous system (CNS) include confusion, hallucinations, and nightmares. Concern about increased risk of neural tube defects with EFV has led to avoidance of this drug in early pregnancy, although accumulating evidence continues to provide reassurance that it can be used safely during pregnancy.[7] The US Food and Drug Administration (FDA) continues to recommend against use of EFV in women who may become pregnant and during early pregnancy, but the DHHS Guidelines and the World Health Organization (WHO) assessment is that EFV is a safe component of ART at any time in pregnancy.[8,9,11] ETR has been approved for children 6 years or older, and it is typically used in combination with PIs and other ARVs in children for whom other ART regimens have failed. RPV is not currently approved for use in children.

Protease Inhibitors

PIs inhibit the HIV protease enzyme, which is required to cleave viral polyprotein precursors and generate functional viral proteins. The protease enzyme is crucial for viral assembly.

PIs have a potent antiretroviral effect, especially when used in combination with NRTIs and/or NNRTIs. Because resistance to PIs requires multiple mutations, some of which reduce viral fitness, PI resistance usually develops slowly. However, compared with NNRTIs, PIs are associated with more long-term toxicity, such as fat redistribution, lipodystrophy syndrome, hyperlipidemia, diabetes mellitus, and hyperglycemia. In children, most PIs require coadministration with a pharmacologic enhancer, usually ritonavir (RTV) because cobicistat (COBI) is not yet approved for use in children. The pharmacologic enhancer inhibits cytochrome P450 (CYP) 3A4 enzymes and increases the concentrations of other PIs. RTV is no longer used in therapeutic doses for anti-HIV activity. The most commonly used PI in children is a coformulation of lopinavir (LPV) and RTV known as LPV/r. Other PIs coadministered with a pharmacologic enhancer include atazanavir (ATV), darunavir (DRV), fosamprenavir (FPV), and tipranavir (TPV).[1] All PIs are metabolized by and/or inhibit enzymes in the CYP system; therefore, attention to potential drug–drug interactions is required.

Entry and Fusion Inhibitors

HIV enters target cells via a multistep process. First, HIV binds to the CD4 receptor, leading to conformational changes in the viral gp120 envelope protein that enable binding to chemokine coreceptors for HIV. Chemokine receptor engagement triggers conformational changes in the HIV gp41 envelope protein, leading to fusion of HIV and the target cell and resulting in delivery to the viral core.

Enfuvirtide (T-20), the only FDA-approved fusion inhibitor, requires twice-daily subcutaneous injections. Maraviroc (MVC) binds to and alters the structure of the CCR5 chemokine receptor, preventing it from being used as a coreceptor by HIV. Because some strains of HIV also can infect cells by using the C-X-C chemokine receptor type 4 (CXCR4) molecule as a coreceptor, MVC is ineffective in individuals who harbor CXCR4-tropic HIV virus or dual-tropic virus (i.e., able bind to both CCR5 and CXCR4). These two drugs are seldom used in children.

Integrase Inhibitors

The three drugs in this class—raltegravir (RAL), dolutegravir (DTG), and elvitegravir (EVG)—inhibit the viral integrase, preventing the strand transfer step that is necessary for integration of the viral genome into the host cell genome. RAL is approved for use in infants as young as 4 weeks of age but requires twice-daily dosing and has a lower barrier to resistance than the newer, once-daily DTG (licensed for ages ≥6 years and body weight ≥30 kg) or EVG (licensed only for adults).

Indications for Initiation of Antiretroviral Therapy

The high mortality rate of HIV-infected infants younger than 12 months of age and the relatively poor ability of the CD4 count and other factors to predict which infants will have rapid disease progression have led to a longstanding recommendation in the United States that ART should commence in all infected infants as soon as they are identified.[1] The CHER trial provided clear evidence in resource-limited settings of the benefit of initiating ART in any infant younger than 12 months of age regardless of CD4 count.[8] In that study, infected infants (6–12 weeks old) with greater than 25% $CD4^+$ lymphocytes were randomized to either initiation of ART or delay until certain defined criteria were met. The fourfold higher mortality rate in the delayed initiation arm led the WHO in 2010 to recommend ART for all infants. Because of the increased mortality and poor predictive capacity of CD4 counts in those aged 1 to 2 years, the WHO also recommended therapy for all 1- to 2-year-old children, although supporting clinical trial evidence was lacking.[11]

Initiation of ART in children older than 1 to 2 years of age was long based on clinical and immunologic staging. Based on evidence from large trials in adults demonstrating clinical benefit of immediate ART initiation irrespective of CD4 count and on availability of expanding safe, potent treatment options for children, ART is now recommended by DHHS and WHO guidelines for all people with HIV infection, including children of all ages.[1,8,12a,12b]

Limited virologic testing capabilities in many countries hinder timely diagnosis of perinatally infected children. Delayed recognition of children with HIV infection still occurs in the United States, usually because of unrecognized perinatal HIV exposure.[12]

Given the need to start multiple agents, comorbid conditions, such as tuberculosis (TB), that require treatment with other medications that can interact with the ARVs, as well as many other complicating factors in the lives of families affected by HIV, should be addressed by intensive counseling and support before treatment begins. Families should be educated about the medications and the critical importance of adherence, and such counseling and support should continue at every visit.

Selection of Antiretroviral Drugs for the Initial ART Regimen

Guidelines for the treatment of pediatric HIV are published and updated regularly.[1,11] Initial therapy with three antiretroviral agents, usually two NRTIs and a PI, an INSTI or an NNRTI, is recommended. The P1060 trial demonstrated that LPV/r-based ART was superior to NVP-based ART for children younger than 3 years old in resource-limited settings[13,14]; however, PENPACT-1 did not demonstrate an advantage of PI-based over NNRTI-based ART in children in higher-resource settings with higher average age and more diverse drug regimens.[15] Factors to consider when deciding on an initial ART regimen for an infant or child include the following[1]:

- Availability of appropriate (and palatable) drug formulations and pharmacokinetic information for the child's age group
- Potency, dosing frequency, food and fluid requirements, and potential short- and long-term adverse effects of the antiretroviral regimen
- Effect of initial regimen on later options
- Presence of comorbidity, such as TB, HBV or HCV infection or chronic renal or liver disease
- Potential interactions of ARVs with other prescribed, over-the-counter, or complementary or alternative medications
- Ability of the caregiver and child to adhere to the regimen
- Results of baseline ARV drug resistance testing

Clinical and Laboratory Monitoring

Table 113.2 displays the schedule of clinical and laboratory evaluations during pediatric HIV management, based on ART status.[1,16] When HIV infection is diagnosed, it is important to stage the disease, evaluate for coinfections and complications, assess the need for OI prevention, provide elements of routine primary health care, and address psychosocial needs. It is important to assess knowledge, attitudes, and potential barriers for taking ART. Adherence counseling begins with readiness assessments before ART initiation and includes monitoring at every clinical encounter once ART has been prescribed. Clinical evaluations are recommended approximately every 3 months for HIV-infected children who have not yet met indications for initiation of ART.

TABLE 113.2

Routine Monitoring Schedule for Management of Children With HIV-Infection by ART Treatment Status

Visit Interval	Monitoring of Treatment Efficacy and Adherence[a]	Toxicity Monitoring, Other Care and Monitoring[a,b]
INITIAL VISIT		
N/A	Assess attitudes and readiness for ART HIV viral load CD4 count and percentage HIV drug resistance genotype	History: complete clinical history, including pregnancy and delivery, OIs, and other HIV-related illnesses; ARV exposure and treatment; immunization record; comprehensive medical and family history Pyschosocial assessment; status of HIV disclosure to child and other family members or contacts Disclosure counseling; guardianship, permanency planning Complete physical examination Growth and nutritional assessment; pubertal and neurodevelopmental assessment; educational assessment General laboratory studies: complete blood count and differential; chemistry panel (liver function, renal function, electrolytes, calcium, phosphate, amylase, lipase); lipid panel[c]; urinalysis (dipstick and microscopic); G6PD-deficiency screening; 25-hydroxy vitamin D level[d] HBsAg, HBsAb, and HBcAb; age-appropriate hepatitis C testing; *Toxoplasma* IgG, varicella IgG TB assessment: exposure, symptoms, STS STI testing (syphilis, chlamydia, gonorrhea) based on maternal history (for infants); STI testing including cervical/anal Pap smear for sexually active youth; reproductive planning and risk reduction counseling for youth
ART INITIATION		
1–2 wk (in	Adherence	Adverse effects history

person or by phone), usually for at least the first 4 wk	counseling and assessment Reinforce medication instructions Viral load (optional)	Targeted physical examination Additional problem-based evaluations Interim clinical and psychosocial history
EARLY ART		
4–8 wk	Adherence counseling and assessment Reinforce medication instructions Viral load CD4 count (optional)	Adverse effects history Targeted physical examination Complete blood count with differential Chemistry panel (liver function, renal function, electrolytes) Additional problem-based evaluations Interim clinical and psychosocial history Intensive, interdisciplinary psychosocial support
STABLE ART		
3 mo	Adherence counseling and assessment Reinforce medication instructions Adjust ARV dosing for growth Consider ARV changes for convenience or tolerability, especially as child learns to swallow pills Viral load HIV viral load CD4 count and percentage[f]	Interim clinical history, including targeted history of adverse effects Targeted physical examination Additional problem-based evaluations Complete blood count and differential Chemistry panel (liver function, renal function, electrolytes, calcium) Drug-specific toxicity monitoring[e] (e.g., phosphate for TDF; amylase, lipase for ddI) Interim psychosocial history Immunization and OI prophylaxis assessment **Every 6–12 mo:** Complete interim history and physical examination Growth and nutritional assessment, pubertal and neurodevelopmental assessment; educational assessment Update family and psychosocial history Disclosure counseling HBsAb (annually, if at ongoing risk) Hepatitis C antibody testing (if at ongoing risk) TB assessment (yearly): history, STS STI testing including cervical/anal Pap smear for sexually active youth Reproductive planning and risk reduction counseling for youth. Optional or in selected patients: 25-hydroxy vitamin D level[e]; bone mineral density assessment (by DXA[e])
SUSPECTED TREATMENT FAILURE		
2–4 weeks (in person and/or by phone)	Adherence counseling and assessment Reinforce medication instructions Confirm drug dosing, food and fasting requirements, interacting drugs Viral load (once at failure, then every ≥8–12 wk if persistent failure	Interim clinical history, including targeted history of adverse effects Targeted physical examination Complete blood count and differential Chemistry panel (liver function, renal function, electrolytes, calcium) Additional problem-based evaluations Interim clinical and psychosocial history Intensive, interdisciplinary psychosocial support

	and ready to start new ART regimen) HIV drug resistance genotype; also phenotype, if multidrug resistance is present	

[a] Monitoring elements performed at each visit interval unless otherwise specified.

[b] No toxicity monitoring is done before ART is initiated.

[c] If lipid panel results are abnormal on a nonfasting specimen, obtain at least one fasting lipid panel per year.

[d] Criteria for vitamin D level and DXA screening are not well established.

[e] Toxicities and monitoring of individual ARV agents are covered elsewhere.

[f] Some experts monitor CD4 count and percentage less frequently (e.g., every 6–12 mo) if adherence is good, CD4 values are greater than the threshold for OI risk, viral suppression is sustained, and clinical status is stable for more than 2–3 yr.

ART, Antiretroviral therapy; ARV, antiretroviral drug; CD4 count, CD4$^+$ lymphocyte count; ddI, didanosine; DXA, dual-energy X-ray absorptiometry; G6PD, glucose-6-phosphate dehydrogenase HBcAb, hepatitis B core antibody; HBsAb, antibody to hepatitis B surface antigen; HBsAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; IgG, immunoglobulin G; N/A, not applicable; OI, opportunistic infection; STI, sexually transmitted infection; STS, skin test for TB; TB, tuberculosis; TDF, tenofovir.

Adapted from Department of Health and Human Services, Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. AIDS Info: Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection. Last updated March 1, 2016. http://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf.

Frequency of visits, assessment, and counseling are intensified at the time ART is initiated, allowing the provider to identify and intervene early in case of problems with adherence or adverse effects. Some patients require counseling every 1 to 2 weeks for several weeks to work through adherence and medication intolerance problems. By 4 weeks after ART initiation, a visit should occur to allow for physical examination and laboratory testing to monitor toxicity and virologic response (see Table 113.2). Additional monitoring may be indicated based on individual antiretroviral toxicity profiles. HIV viral load should be measured to confirm the expected response to ART. Clinical assessments should continue every 4 to 8 weeks or at shorter intervals if there are problems with adherence, intolerance, laboratory abnormalities, or lack of virologic response. In an uncomplicated case, encounters occur at 1 to 2 weeks, at 4 weeks, and at 12 weeks after initiation.

Successful ART is expected to reduce viral load by at least 1 log from baseline at 8 to 12 weeks, and a viral load of less than 200 copies/mL should be attained by 6 months.[1] Children whose pretreatment viral load is extremely high (>10^6 copies/mL) may take longer to achieve viral load suppression, but they should nonetheless demonstrate a 1-log drop in viral load by 12 weeks and a consistent pattern of declining viral load measurements thereafter. For children who begin ART with CD4 counts greater than the age-specific threshold that would indicate immunosuppression,[17] successful ART is expected to be associated with sustained or increased CD4 counts. Infants and children whose CD4 counts are depressed at ART initiation should achieve CD4 counts greater than the level associated with immunosuppression within 6 to 12 months, although those with severe immunosuppression at ART initiation may take 2 years or longer to reach healthy CD4 counts, and some may never achieve CD4 reconstitution.[18]

Once patients have a documented response to therapy on stable ART, routine monitoring visits should take place approximately every 3 months with the goals of assessing adherence, documenting ongoing treatment success (by viral load and CD4 count), evaluating for toxicity, and ensuring that other aspects of comprehensive care are provided. Some experts monitor CD4 count every 6 to 12 months in those children who have maintained CD4 counts greater than the threshold for OI risk, sustained viral suppression, and stable clinical status for longer than 2 to 3 years.[1,19]

Illnesses that occur during the initial 3 to 6 months of treatment do not always represent treatment failure, especially in the context of good virologic response; such illnesses may be the result of incomplete reversal of baseline immunosuppression or an immune-reconstitution inflammatory syndrome (IRIS) that occurs as an exaggerated or unmasked response to an infection in the context of an imbalanced, recovering immune system.[20] Mycobacterial infections, toxoplasmosis, cryptococcosis, and varicella-zoster virus infection account for most IRIS events; in lower-resource settings, TB and bacille Calmette-Guérin (BCG) disease are especially common. Noninfectious IRIS syndromes, such as sarcoidosis and inflammatory response to Kaposi sarcoma, can occur. In addition to management of the underlying infection or condition, IRIS may require treatment with nonsteroidal anti-inflammatory agents and, when more severe, with systemic corticosteroids. ART rarely is withheld and only in the most severe cases. Mortality is most often related to complications of CNS IRIS syndromes.

Treatment failure can manifest as lack of virologic suppression, decline or inadequate increase in CD4 count, or new HIV-related clinical illness. The most common manifestation of treatment failure is lack or loss of virologic suppression; the most common underlying reason is medication nonadherence. Drug resistance can be a primary cause of treatment failure or can emerge during periods of poor virologic control attributable to nonadherence. Poor virologic response or relapse after virologic suppression merits prompt reassessment. Isolated episodes of low-level viremia (<500 copies/mL) usually do not represent virologic failure.[21] However, repeated detection of even low-level viremia may signify failure.[19] If virologic failure is confirmed, assessment and counseling visits should emphasize adherence improvement, evaluate for drug resistance with HIV genotypic testing, confirm ARV dosing and food and fasting requirements for individual ARVs, and exclude use of other drugs that interfere with absorption, metabolism, or action of ARVs (e.g., proton-pump inhibitors that reduce absorption of ATV). Changing to a new ART regimen should be undertaken only after these problems—especially adherence—have been addressed.

Infection Prevention: Immunizations and Chemoprophylaxis

Chapter 112 provides a detailed discussion of prevention and management of infectious disease complications of HIV infection, and specific guidelines are published and updated periodically.[2] Indications for chemoprophylaxis against OIs and eligibility for vaccines should be reviewed at every clinical evaluation.

All HIV-infected infants require prophylaxis against *Pneumocystis* pneumonia (PCP) caused by *P. jirovecii* regardless of clinical, immunologic, or treatment status. Beyond the first year of life, indications for OI chemoprophylaxis should be based on the CD4 count obtained at the prior visit, interpreted according to normative values by age. Declines in CD4 values, resulting in new need for OI chemoprophylaxis, are most likely to occur in children who are not yet receiving ART.

Primary and secondary OI chemoprophylaxis for PCP and for toxoplasmosis can be safely discontinued in children older than 1 year of age who are receiving stable ART and have immune reconstitution.[2] It is important to assess for the need to restart prophylaxis at each HIV monitoring visit.

Specific recommendations for routine immunization have been developed for HIV-infected children[2] because the safety, immunogenicity, efficacy, and protective durability of vaccines may be different from those observed in non–HIV-infected children.[22] These differences vary by specific vaccine and by demographic and clinical characteristics of the vaccine recipients, including use of ART and degree of immunosuppression.

The increase in HIV viral load and decline in CD4 count that can follow immunization are transient and without clinical consequences. Although increased mortality was reported after administration of pneumococcal polysaccharide vaccine compared with placebo in a trial involving HIV-infected African adults who were not receiving ART,[23] there is no evidence of increased toxicity with use of pneumococcal or other non-live vaccines in adults receiving ART or in HIV-infected children.[22] Therefore, non-live vaccines are regarded as safe for use in HIV-infected children. Because serious and even fatal illnesses have occurred in severely immunocompromised HIV-infected children after administration of live virus vaccines, measles, mumps, rubella, and varicella vaccines are not recommended for such children, although they should be used in those without severe immunosuppression. Increasing evidence suggests that both rotavirus vaccines[24] and cold-adapted live-attenuated intranasal influenza vaccine can be used safely in HIV-infected children.[25] BCG vaccine should not be given to infants with known HIV infection or to those with perinatal HIV exposure accompanied by symptoms suspicious for HIV infection. However, BCG vaccine may be given to infants who are asymptomatic, including those of undetermined HIV status born to HIV-infected mothers, in countries with high TB burden and established neonatal BCG vaccination programs.[26]

HIV-infected children demonstrate blunted humoral responses compared with uninfected children. Impaired response is particularly common in children with advanced HIV disease, lower CD4 counts, higher viral loads, and lack of ART.[22] With effective ART, most HIV-infected children respond adequately, although not as well as uninfected children. Potential strategies that have been explored to optimize protection of HIV-infected children include additional vaccine doses in primary series, higher-titer vaccine doses, more frequent booster doses, postimmunization confirmation of serologic response, and reimmunization after immune reconstitution. Most children who initiate ART beyond infancy lack immunity related to vaccines they received before ART.[27,28] Older children who received measles-mumps-rubella (MMR) vaccine before starting effective ART should have MMR doses repeated once they are receiving stable ART and have improved CD4 counts.[29,30] Routine reimmunization may be indicated for other vaccines in such children, but further evidence is needed.[27]

Growth and Nutrition

With effective ART, HIV-infected children in the United States rarely suffer the AIDS-defining growth failure and severe malnutrition that were typical in the pre-ART era. These manifestations, now observed largely in those patients who are failing ART, portend a poor prognosis. High-calorie supplementation (orally or by gastrostomy tube) and appetite stimulants may be used as adjunctive, supportive therapy, but the most important intervention is institution of effective ART. Whereas effective ART routinely improves weight gain and linear growth, normal final height may not be attained, especially in children who are already stunted when ART is begun.[31]

Growth failure that occurs in the setting of successful ART merits a comprehensive evaluation, including for causes unrelated to HIV infection. There are no established associations of specific ARVs and growth failure, but alterations in body appearance and fat distribution and metabolic derangements in ART-treated children are common. Body mass index (BMI) should be monitored routinely, and overweight children should be given nutrition and exercise counseling.

Evidence of delayed puberty in HIV-infected children is limited largely to the pre-ART era. More recent data suggest that pubertal delay among children receiving ART is less common and is largely confined to those with poor response to ART.[32]

Vitamin D deficiency is common in HIV-infected children; ensuring vitamin D sufficiency and adequate intake of calcium should be emphasized.

Disclosure

Developmentally appropriate disclosure of HIV infection status to children is recommended strongly.[33,34] Informing and educating children about their HIV infection takes place in stages, often over years, beginning with general information about reasons for taking medicine and having an infection. Discussing HIV by name requires the child to have an intellectual ability to understand the information and a capacity to understand the principle of keeping medical information private, usually at 8 to 10 years of age. A multidisciplinary team should provide ongoing counseling to parents and other caregivers about the purpose and process of disclosure. Some parents prefer to have disclosure discussions with their children at home, whereas others prefer to have staff present to participate in or even lead the disclosure discussions. Delaying disclosure until older ages increases the risk of inadvertent or unplanned disclosure and poor outcomes. Awareness of HIV status before onset of sexual activity is especially important for prevention of secondary transmission.

Consequences of Infection and Antiretroviral Therapy by Organ Systems

Neurologic Function

HIV infection commonly affects both the CNS and the peripheral nervous system. In the pre-ART era, the impact of infection of the CNS was devastating in infants and children, with up to 50% of infected infants developing encephalopathy with substantial morbidity and mortality. Pathologic findings have included focal cerebral mass lesions, myelopathies, myopathies, seizures, cerebral vascular accidents, and peripheral neuropathies. Since the advent of ART, encephalopathy has almost disappeared.[35,36] However, an emerging concern is for more subtle CNS problems, such as cognitive deficits, problems with attention, and psychiatric disorders.[37,38] The etiology of these problems is not completely understood and likely is multifactorial. Potential causes include ongoing CNS infection or ongoing damage secondary to the initial CNS infection,[39] inflammatory changes,[40] ARV toxicities,[41] HIV- and ARV-related metabolic derangements, other exposures (e.g., in utero exposure, current substance use), and social and demographic influences.

Many of the NRTIs can exacerbate or trigger peripheral neuropathy, although peripheral neuropathy also can occur in HIV-infected children who are not receiving ARVs. EFV can cause impaired concentration, sleep disturbances, anxiety, vivid dreams, nightmares, and psychosis. In most patients, these symptoms are self-limited or manageable with nighttime administration of EFV; EFV probably should not be used in children with psychiatric disorders.

Cardiovascular Health

Cardiomyopathy caused by ARVs (especially ZDV) and HIV was a major cause of morbidity and mortality in the pre-ART era.[42] In the ART era, the proportion of deaths due to cardiomyopathy has remained relatively stable, but the absolute number of cases has declined along with the dramatic decreases in overall mortality.[43] An emerging concern is the long-term effect of dyslipidemia and other metabolic derangements in children with well-controlled HIV disease. HIV itself is known to cause dyslipidemia, marked primarily by low concentrations of high-density lipoprotein. A substantial proportion of perinatally infected children, especially those treated with NRTIs and PIs, have dyslipidemia (elevated cholesterol, elevated triglycerides, or both), other metabolic derangements (e.g., insulin resistance), and fat redistribution (with an overall appearance of peripheral wasting and central obesity that is associated with increased risk of cardiovascular disease).[44,45] Appropriate prevention and management include standard recommendations about diet and exercise. The roles of statins and other pharmacologic therapies that have been recommended for other high-risk pediatric groups[46] have not been evaluated fully. Consideration may be given to substitution of lipodystrophy-promoting ARVs with ARVs associated with less lipid and metabolic derangement (e.g., RAL in place of LPV/r).

Another potential cardiac complication of the specific PIs ATV LPV/r, saquinavir (SQV), and RTV is prolongation of the PR interval and other conduction problems. Caution should be exercised when using these agents in patients known to have preexisting conduction problems and in those receiving other drugs that also are associated with conduction problems.

Hepatic Function

All perinatally HIV-infected children should be evaluated for HBV and HCV infections. The rate of HCV maternal–infant transmission is estimated to be 4% for HIV-uninfected women but rises to about 20% in women with HIV/HCV coinfection.[47] It is not clear whether the rate of HBV maternal–infant transmission is different if the mother also is HIV-infected. Infants of HBV/HIV-coinfected women should receive the same HBV preventive management as infants of HBV-monoinfected women. HBV surface antigen and HCV antibody testing also should be performed in older HIV-infected children for whom maternal information is lacking.

Several ARVs, including 3TC, emtricitabine (FTC), and TDF, have activity against HBV. For this reason, TDF is included routinely in ART regimens for HBV/HIV-coinfected older children; its use in younger children is limited by potential adverse effects.[1] Once HBV-active drugs are initiated, caution is advised against discontinuing these drugs because flares of hepatic inflammation have been reported.

In children who have persistent, severe immunosuppression (CD4 counts <50–100/mm^3 or <15%), several OIs can involve the biliary system and produce a syndrome of right upper quadrant pain, fever, direct hyperbilirubinemia, and elevation of serum aminotransferase levels. Ultrasonography or other imaging is indicated. Detection of the offending pathogen may require direct aspiration, biopsy, and/or endoscopic retrograde cholangiopancreatography (ERCP)-guided sphincterotomy and fluid sampling. Ascending bacterial cholangitis and obstructive conditions also should be considered. Such biliary problems are rare in children receiving ART.

Tests of hepatic inflammation and function are part of routine monitoring. Jaundice due to indirect hyperbilirubinemia is commonly associated with ATV. This benign drug effect is thought to be related to inhibition of a uridine diphosphate glucuronyltransferase. At first occurrence, it is important to exclude elevated direct bilirubin and increased hepatic transaminases, abnormalities that would suggest a different etiology. Even with continued use of the precipitating ARV, the indirect hyperbilirubinemia may abate. Hepatic transaminase elevation is common in HIV-infected children, and frequently no specific explanation is found; HIV infection itself, ARVs (especially NNRTIs), non-ARV agents, and hepatotropic viral infections should be considered. Persistent or moderate elevations deserve further evaluation. Intercurrent viral infections (e.g., Epstein-Barr virus, enteroviruses) and effects of ARVs and non-ARV agents are the most common causes. It is important also to consider HBV and HCV infection, withdrawal of HBV-active drugs in HBV-coinfected children, and HBV- or HCV-related IRIS. There is concern that ongoing mild or subclinical liver inflammation may pose a long-term risk of progressive liver dysfunction, liver fibrosis, and cirrhosis.[48]

Renal Health

In the pre-ART era, HIV infection frequently caused kidney disease. HIV-associated renal disease has been classified into four groups: acute tubular disease, immune-mediated glomerulopathies, thrombotic microangiopathies, and HIV-associated nephropathy. In the ART era, the proportion of deaths due to renal disease has increased relatively; fatalities probably reflect end-stage HIV disease.[43] The rate of glomerular disease has decreased, and the rate of proteinuria, as high as 33% in the pre-ART era, has fallen to less than 10% in the ART era.[49,50] Specific ARVs, such as TDF and many of the PIs, are associated with renal disease. TDF-associated renal disease is a tubulopathy characterized by proteinuria, glycosuria, and renal phosphate wasting. Treatment with some PIs has been associated with renal calculi.[51] In most cases, these toxic effects on the kidney are reversible with discontinuation of the offending ARV.

Appropriate monitoring for kidney disease includes measurements of serum creatinine and other electrolytes along with urinalysis before ARVs are started and then periodically during treatment. More intensive monitoring may be necessary for those receiving TDF.[52] Renal complications can develop as an insidious, progressive, chronic process exacerbated by nephrotoxic agents or other metabolic effects of longstanding HIV infection.[53] All of the NRTIs (except ABC) and TDF are excreted by the kidney and require appropriate dose adjustments in the setting of impaired renal function.

Bone Health

HIV infection in adults increases the risk of osteonecrosis (avascular necrosis), a condition that results from ischemic death of the cellular elements of bone.[54] The femoral head is affected most commonly, but other involved structures may include humeral heads and wrist bones. HIV-infected children appear to be at increased risk, with an approximately 0.2% prevalence of avascular necrosis of the hip.[55] The most important osteonecrosis risk factor is corticosteroid use, which can be exacerbated by PI-mediated alterations in corticosteroid metabolism. Other risk factors include alcohol use, hemoglobinopathies, hyperlipidemia, pancreatitis, low bone mineral density (BMD), and hypercoagulable states. Specific risk factors for HIV-infected children have not been determined. Limp, hip pain or periarticular pain and tenderness, and limited range of motion at affected joints are typical. Imaging is used to confirm the diagnosis. Less advanced osteonecrosis can be managed with avoidance of weight bearing and use of analgesics, but surgical intervention often is required; consultation with an orthopedic specialist should be obtained early. Corticosteroid use and alcohol intake should be minimized.

Decreased BMD is recognized as an emerging metabolic complication of HIV infection in adults and children.[56,57] Declining bone mass (osteopenia) frequently precedes osteoporosis. Decreased BMD occurs in about 15% to 20% of HIV-infected adults and children in the ART era. Increased risk of fracture has been demonstrated in HIV-infected adults compared with uninfected adults,[58] but such findings have not been reported for children. The impact on bone health of perinatally HIV-infected children will likely not be understood fully until these children reach adulthood because of the normal maturational changes in BMD. The dual concern is that infected youths may not attain a normal peak bone mass in early adulthood and will continue to have high rates of ongoing bone loss, which would lead to high rates of osteoporosis and fractures in adulthood.

The causes of low BMD and osteoporosis in HIV-infected children and adolescents, in addition to HIV-specific factors such as effects of HIV infection and ARV use, include low BMI, malnutrition, corticosteroid use, and vitamin D insufficiency; in older adolescents, smoking, alcohol consumption, or use of medroxyprogesterone injectable contraception may be a cause. Lower BMD was observed in HIV-infected patients in the pre-ART era. Initiation of ART has been associated repeatedly with loss of BMD. Specifically implicated ARVs include d4T, TDF, and PIs.

There is no recommendation at the present time for routine radiographic assessment of BMD in children and youths.[1,56] Given the high rates of vitamin D insufficiency in children with HIV infection, periodic assessment of vitamin D status is recommended.[59] Ensuring calcium and vitamin D sufficiency, encouraging weight-bearing exercise, and minimizing use of tobacco, alcohol, corticosteroids, and other drugs that compromise bone health are important interventions for maintenance and restoration of bone health. Substitution of TDF with a different ARV—balanced against the feasibility of maintaining virologic suppression without TDF—may be warranted if very low BMD or osteoporosis is diagnosed.

Pulmonary Conditions

In the pre-ART era, pulmonary infections in HIV-infected children were common. PCP was a common presentation for infants with unrecognized HIV infection. PCP and recurrent bacterial pneumonia are now uncommon in the United States and occur predominantly in children whose severe immunosuppression is a result of lack of effective ART. Asthma may be more common in HIV-infected children with increasing use of ART.[60]

TB commonly complicates HIV infection in children who live in TB-endemic areas. Although this is less of a problem for children in the United States, HIV-infected US children are at increased risk of exposure to *Mycobacterium tuberculosis* if they live with HIV-infected, immunosuppressed adults with TB; have immigrated from TB-endemic areas; or have household contacts who immigrated from TB-endemic areas. HIV-infected children should have annual screening for TB risk and symptoms as well as testing with a tuberculin skin test or interferon γ release assay. Once infected with *M. tuberculosis*, HIV-infected children are at increased risk of developing TB disease, especially if CD4 counts have not been preserved or restored by ART.

Lymphocytic interstitial pneumonitis (LIP) is a chronic lymphoproliferative disorder that was observed in about one third of HIV-infected children in the pre-ART era (see Fig. 111.3 in Chapter 111). LIP can lead to bronchiectasis and progressive pulmonary decompensation. Distinguishing the radiographic appearance of LIP from that of TB or PCP can be difficult. Epstein-Barr virus has been implicated in the pathogenesis of LIP, but the etiology is not definitively established. Episodic pulmonary exacerbations respond to systemic corticosteroids. LIP appears to be both prevented and treated by ART.[61]

Hematologic Abnormalities

Anemia, thrombocytopenia, and neutropenia are observed commonly in HIV-infected children. These abnormalities can be related to the HIV infection itself, toxicity of ARVs or other commonly used drugs, malnutrition or micronutrient deficiency, superinfection (e.g., parvovirus, B19, *Mycobacterium avium* complex), or malignancy.

Anemia usually results from direct bone marrow suppression by HIV or from autoimmune hemolytic anemia. Both typically improve with ART, although control of autoimmune hemolytic anemia may require use of corticosteroids. Anemia related to concomitant infection, malignancy, or other conditions improves with treatment of the underlying condition. Drug-related anemia usually is the result of marrow suppression (e.g., due to ZDV, cotrimoxazole) but also can be related to hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient patients taking drugs such as dapsone or sulfonamides. ZDV-related anemia is common and usually is macrocytic. Erythropoietin injections have been used to mitigate severe nonhemolytic anemia and avoid transfusions in children without an alternative to ZDV or an immediate option for treatment of an underlying condition, but this approach is rarely needed now.

Neutropenia in HIV-infected children does not seem to carry the same risk of infection as neutropenia in children with malignancies. ZDV is the most common drug-related cause. Neutropenia also can be caused by direct effects of untreated HIV infection, other drugs, intercurrent infections, or malignancy. Effective HIV treatment, substitution of offending drugs, and/or treatment of underlying conditions usually is sufficient. Injections of granulocyte colony-stimulating factor (G-CSF) have been effective for severe or persistent neutropenia but are rarely needed today.[1]

Thrombocytopenia is more likely the result of HIV infection than the result of HIV treatment. Thrombocytopenia typically responds to ART and is uncommon among children receiving effective ART. Other causes include indinavir (IDV), non-ARV agents (e.g., cotrimoxazole), opportunistic and non-opportunistic infections, recent live-virus immunizations, and malignancy. Severe thrombocytopenia has been managed successfully with the same therapeutic approaches as for HIV-unrelated immune thrombocytopenic purpura.[1]

Lactic Acidosis and Mitochondrial Dysfunction

NRTIs/NtRTIs inhibit mtDNA synthesis and impair mitochondrial function in vitro. HIV itself also can cause mitochondrial dysfunction. Clinical manifestations are broad, ranging from asymptomatic elevations in lactic acid (2.1–5.0 mmol/L); to a combination of symptoms and signs including fatigue, weakness, myalgia, abdominal pain, and dyspnea; to severe multiorgan involvement (hepatic toxicity, pancreatitis, and respiratory failure) with elevated lactic acid concentrations. Mitochondrial toxicity also can play a role in peripheral neuropathy, cardiomyopathy, and CNS toxicity. Because asymptomatic elevations of lactic acid are common and of uncertain significance, routine assessment of lactic acid levels is not recommended. However, measurements should be performed whenever signs or symptoms of lactic acidosis are present.[1]

In the setting of symptomatic lactic acid elevations, all ARVs should be discontinued. After resolution of symptoms and normalization of lactic acid concentrations, a new ARV regimen that does not include the likely offending agents should be started. Although in vitro data suggest that ddI and d4T are most likely—and 3TC and TDF are less likely—to cause lactic acidosis, the clinical situation can be more complicated.[62,63] Therefore, NRTI/NtRTI-sparing regimens may be preferred in a patient who has experienced mitochondrial toxicity and lactic acidosis.

Malignancies

HIV-infected adults are at high risk for several cancers, including Kaposi sarcoma and non-Hodgkin lymphoma. In the ART era, HIV-infected adults are much less likely to develop Kaposi sarcoma, but because of improved survival and other risk factors, a much broader array of malignancies is now seen. Cancer is a leading cause of death among adults infected with HIV in the United States.[64] Cancer rates are low in infants and children infected with HIV but still higher than in the general pediatric population.[65]

Reproductive Health

By 19 years of age, 17% of perinatally infected girls in one cohort had been pregnant at least once.[66] In this same cohort, 27% of 13- to 24-year-old girls were sexually active. Those who were sexually active had higher viral loads and lower CD4 counts, factors that increase the risk of HIV transmission.

Whereas screening for cervical dysplasia (i.e., by Pap smear) is generally deferred in adolescents (regardless of the age at onset of sexual activity) until age 21 years, sexually active HIV-infected adolescents should undergo cervical cytology screening twice during the first year after sexual activity onset and annually thereafter.[2,67] Human papilloma virus (HPV) vaccines are safe and immunogenic in perinatally HIV-infected children and youths[68]; HPV vaccine should be offered to all children, preferably by 11 years of age. Even those with evidence of HPV disease should receive HPV vaccine. Anal dysplasia screening (by anal Pap smear) also may be beneficial for HIV-infected women and men who have sex with men.[2]

Routine HIV care for perinatally infected adolescents should include regular reproductive health screening and counseling. Discussion and prevention counseling should include current and planned sexual activity; reducing the risk of acquiring and transmitting sexually transmitted infections (STIs), including HIV infection; partner disclosure; screening for STIs and for HPV-associated dysplasia; and pregnancy planning and contraception. Condoms are recommended to prevent transmission of HIV, HPV, and other STIs and for pregnancy prevention. Many forms of hormonal contraception can be used safely and effectively by HIV-infected women, but providers should be aware of potential drug interactions, especially between many PIs and oral contraceptives.[69] Most often, the infected youth's partner is not HIV-infected; periodic HIV testing and counseling about preexposure prophylaxis (PrEP) for the partner is recommended, and consultation with an obstetrician can be helpful for counseling about approaches to safe conception for the HIV-discordant couple.

International Settings

In resource-limited countries, HIV remains a devastating problem, but improving access to ARVs is transforming the pediatric HIV epidemic in those countries, as it has in the United States. Numerous studies have shown that despite treatment initiation in children at more advanced stages of disease, response to ART in resource-limited settings is similar to results in the United States and Europe.[70] Nevertheless, many challenges remain, including the cost of treatment, limited infrastructure for medical care, nutritional deficiencies and food insecurity, and comorbid conditions, especially TB and malaria, that are rarely seen in HIV-infected children in the United States.

Transition of Care

The advent of effective ART has transformed perinatal HIV from a progressive, fatal infection into a chronic disease. In addition to the possibility of cardiovascular and other long-term complications, survivors of perinatal HIV infection confront the same challenges of adolescence and adulthood faced by peers without HIV infection. Rather than focusing just on survival and avoidance of opportunistic illnesses, counseling of HIV-infected adolescents and young adults must also focus on school success and career choices, reproductive health and plans for marriage and family, and the transition to adult medical care. Transition to adult medical care takes time and advance planning because the pediatric and adult chronic care models are different. Awareness of patient and provider factors that facilitate or enhance transition can inform programs for perinatally HIV-infected young adults to enroll successfully in adult medical care.[71] Routine advance care planning with HIV-infected youths and their families is as important as in any youth with chronic illness and has been shown to be well received and beneficial.

Classification of Bacteria

Joseph W. St. Geme III, Katherine A. Rempe

The ability to discriminate among distinct groups of organisms and to communicate with a common language about organisms in the context of disease is essential for clinical microbiologists and for physicians caring for patients. The official taxonomic ranks for naming bacterial organisms are kingdom, division, class, order, family, genus, and species. A bacterial *species* is defined as a distinct group of organisms that share a constellation of properties. This definition is somewhat subjective, and as new data become available, reclassification is necessary occasionally.

Identification by Phenotypic Characteristics

Historically, bacterial classification has been based on phenotypic characteristics. A useful first approach to classification was developed in 1884 by Christian Gram, who observed that some bacteria retain crystal violet dye after decoloration with ethanol and others do not; in this test, now called Gram staining, the former group of bacteria remain blue and are called *gram positive*, whereas the latter appear red and are called *gram negative*. These staining characteristics reflect differences in cell wall structure. As shown in Fig. 114.1, gram-positive cells have a relatively simple cell wall composed of an inner membrane and a surrounding peptidoglycan layer between 30 and 200 molecules thick. The gram-positive cell wall also contains teichoic acids and lipoteichoic acids, which are water-soluble polymers of polyol phosphates. Gram-negative organisms have a more complex cell wall characterized by the presence of an inner membrane, a surrounding peptidoglycan layer one to two molecules thick, and an outer membrane (see Fig. 114.1). The outer membrane contains lipopolysaccharide (endotoxin), which is unique to gram-negative organisms. The compartment between the inner and outer membranes, called the periplasm, contains a number of degradative enzymes and transport-related proteins.

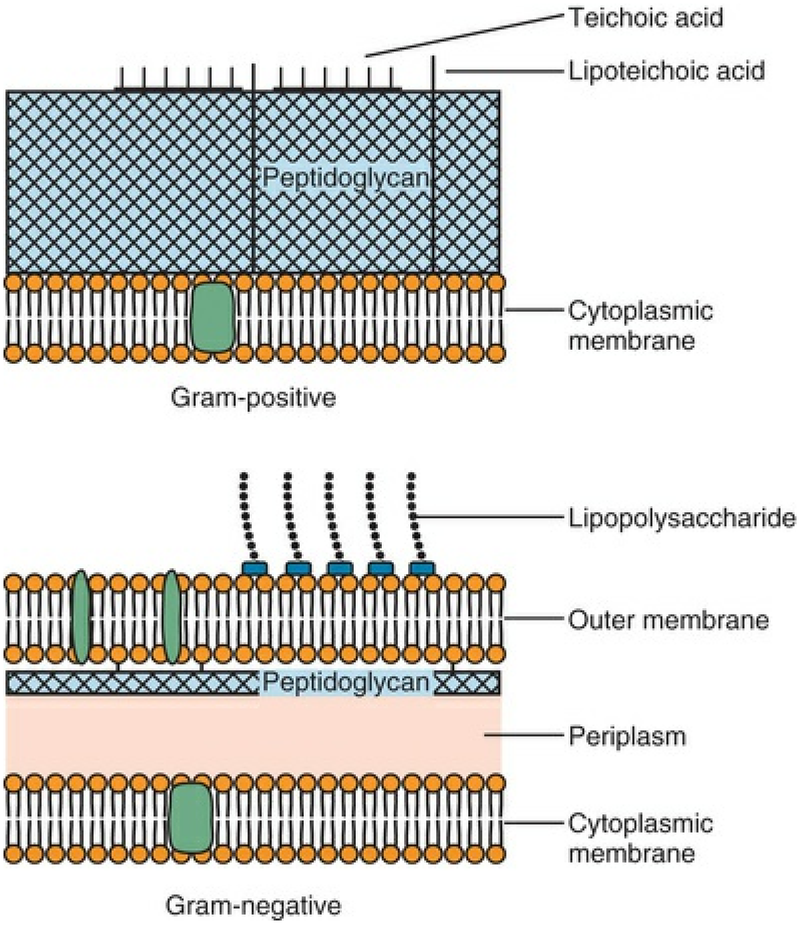

FIGURE 114.1 Schematic diagram of the cell wall structures of gram-positive and gram-negative bacteria.

Whereas most bacteria are gram-positive or gram-negative, some stain poorly or fail to stain at all with Gram reagents. Examples are mycobacteria, some actinomycetes, treponemes, rickettsiae, anaplasmae, chlamydiae, and mycoplasmas. Mycobacteria possess a complex cell wall that is rich in lipids; they have been referred to as *acid fast* because of their resistance to decolorization with acid solutions. These organisms are best visualized microscopically with Ziehl-Neelsen or Kinyoun acid-fast stain. Most actinomycetes are gram positive, but *Nocardia* and *Rhodococcus* characteristically take up Gram stain irregularly. They have a cell wall structure similar to that of mycobacteria, and, like the mycobacteria, they are acid fast.

The family Treponemataceae contains five genera, namely *Treponema, Borrelia, Leptospira, Brachyspira,* and *Spirillum.* The treponemes generally do not stain with Gram reagents or other standard laboratory stains and usually are best seen with darkfield microscopy. Members of the family Rickettsiaceae and the family Anaplasmataceae *(Ehrlichia, Anaplasma, Wolbachia,* and *Neorickettsia)* possess a cell wall typical of gram-negative bacilli but react weakly with Gram stain and are visualized optimally with Giemsa or Gimenez stain. Members of the family Chlamydiaceae *(Chlamydia trachomatis, Chlamydophila psittaci,* and *Chlamydophila pneumoniae)* are obligate intracellular organisms that possess inner and outer membranes similar to those of gram-negative bacteria but lack a peptidoglycan layer and do not take up Gram stain. The two important members of the family Mycoplasmataceae are *Mycoplasma* and *Ureaplasma.* Mycoplasmas do not have a cell wall; their cytoplasmic contents are enclosed only by a well-developed plasma membrane.

Cellular morphology also plays an important role in classification. Bacteria can be separated into five major groups on the basis of morphology as viewed through the light microscope. Bacteria that are spherical or oval in appearance are described as *cocci.* Those that are rod-like or cylindrical are referred to as *bacilli.* Those with a comma-like or curved rod appearance are referred to as *vibrios*. Bacteria with a helical or more undulating appearance are called *spirochetes* if they are flexible or *spirilla* if they are rigid.

After cell division, the cell wall between daughter cells in some species may not separate completely, giving rise to various cell arrangements. These cell arrangements are typically distinctive and may be helpful in identifying related organisms. Common arrangements are cocci in pairs, cocci in chains, cocci in irregular clusters, cocci in packets of four or eight (called *sarcina*), bacilli in pairs, bacilli in chains, unusually short bacilli (called *coccobacilli*), and bacilli with tapered ends (called *fusiform bacilli*).

A wide range of other phenotypic characteristics also are employed for the purpose of bacterial classification. For example, aerobic and facultative anaerobic organisms are distinguished from strictly anaerobic organisms, and spore-forming bacteria are distinguished from non–spore-forming species. Additional useful properties are carbohydrate fermentation ability, susceptibility to antibiotics and inorganic compounds, and reactivity with well-defined serologic reagents.

Identification by Molecular Techniques

Beyond phenotypic characteristics, molecular analysis also plays a major role in determining phylogenetic relationships among organisms and in classifying bacteria. The historical standard in this respect is DNA-DNA hybridization, which allows the total DNA from one organism to be compared with the total DNA of any other organism.[1] This technique involves incubating single-stranded DNA from one strain with single-stranded DNA from a second strain and assessing the formation of a double-stranded DNA molecule. DNA reassociation is a specific, temperature-dependent reaction. The optimal temperature for DNA reassociation is 25°C to 30°C below the temperature at which native double-stranded DNA is denatured into single strands. Experience with several hundred species has led taxonomists to conclude that organisms with 70% or greater DNA-DNA relatedness belong to the same species. Occasionally, the 70% species-relatedness rule has been ignored when the existing nomenclature is both deeply ingrained and useful. Examples include *Escherichia coli* and the four species of *Shigella*. These organisms all are more than 70% related and should therefore be grouped into a single species instead of the present five species in two genera. However, to avoid confusion among the medical community, no change has been made.

Mole percent guanine plus cytosine (G + C) content and genome size are two other measurements of DNA that often are helpful in classifying organisms.[2] The G + C content in bacterial DNA ranges from about 25% to about 75%. The G + C percentage is specific for a given species but is not unique to that species. Therefore, two strains with similar G + C contents may or may not belong to the same species. On the other hand, if the G + C contents are very different, the strains cannot be members of the same species. *Genome size,* or the molecular mass of bacterial DNA, ranges between 1×10^9 and 8×10^9 daltons. In certain circumstances, genome size determinations can distinguish between groups. Such determinations were used to distinguish *Legionella pneumophila* from *Bartonella quintana. L. pneumophila* has a genome size of 3×10^9 daltons, whereas the *B. quintana* genome is roughly 1×10^9 daltons.

In a number of cases, multilocus enzyme electrophoresis (MEE) has been applied to classify bacteria.[3] This method detects differences in the electrophoretic mobilities of individual soluble metabolic enzymes. The cellular proteins of an organism are separated by starch gel electrophoresis, and the individual enzymes are detected with the use of specific substrates. Variations in electrophoretic mobility of a given enzyme typically reflect amino acid substitutions that alter protein charge; these variations thus represent different alleles of the gene encoding the enzyme. In analyses of a relatively large number of enzymes, a positive correlation between estimates of relatedness obtained by MEE and by DNA hybridization of whole chromosomal DNA has been demonstrated. Therefore, it is possible to use MEE to determine the level of relatedness of two strains or a group of strains. This method has been particularly useful in yielding quantitative data about the relationships among organisms within a given species. In addition, it has provided insights into bacterial evolution.

Two additional methods are useful to determine genetic relatedness between strains and to characterize the population structure of a given species: pulsed-field gel electrophoresis (PFGE) and amplified fragment length polymorphism (AFLP) analysis.[4,5] PFGE has been the accepted gold standard for many species and involves extraction of chromosomal DNA and then digestion of the DNA with a rare-cutting restriction enzyme, giving rise to a number of large (80–100 kb) fragments, which can be separated by applying an electrical field alternatively in two directions. The critical experimental variable is the *pulse time,* which is defined as the time during which a field is applied in one direction before it is abruptly switched to another direction. Each strain gives rise to a reproducible pattern of bands (a fingerprint), and the number of bands shared between strains provides a measure of relatedness. AFLP analysis involves extraction of genomic DNA and then digestion of this DNA with two restriction enzymes. Subsequently, two different double-stranded oligonucleotide adapters are added to the digested DNA, one compatible with the first restriction enzyme and the other compatible with the second enzyme. After ligation, an aliquot of the DNA sample is subjected to polymerase chain reaction (PCR) amplification under highly stringent conditions with adapter-specific primers that have an extension of one to three bases at their 3-prime ends, running into the unknown chromosomal fragment. An extension of one base (e.g., adenine) in one primer results in amplification of one-fourth of the ligated fragments (e.g., those with a thymine but not those with adenine, guanine, or cytidine at the complementary position), whereas an extension of two or three bases results in amplification of a smaller fraction of fragments. After polyacrylamide gel electrophoresis, a highly informative pattern of 40 to 200 bands is obtained.

The molecular technique that has taken on greatest importance for classifying bacteria is 16S (small subunit) ribosomal RNA (rRNA) gene sequencing. The 16S rRNA folds in a precise fashion with the large subunit rRNA to form ribosomes. *Ribosomes* are highly conserved structures found in all living cells that perform the crucial task of protein synthesis. Because the genes for 16S rRNA contain some sequences that have been highly conserved through the course of evolution and others that are highly variable, 16S rRNA gene sequencing can be used to determine evolutionary and genetic relationships among organisms.[6] A further attribute of 16S rRNA gene sequencing is that cultivation of the organism is not required; for example, through the use of PCR and oligonucleotide primers that correspond to conserved regions of the bacterial 16S rRNA gene, a stretch of bacterial DNA can be amplified directly from diseased tissue or any other relevant source.[7] The variable regions of the resultant DNA sequence form the basis for specific phylogenetic analysis. In general, consensus primers can be designed for any discrete group of organisms with common ancestry. On the basis of 16S rRNA sequence comparisons, the evolutionary relationships among all known extant bacterial species can be represented in a phylogenetic tree (Fig. 114.2).[7]

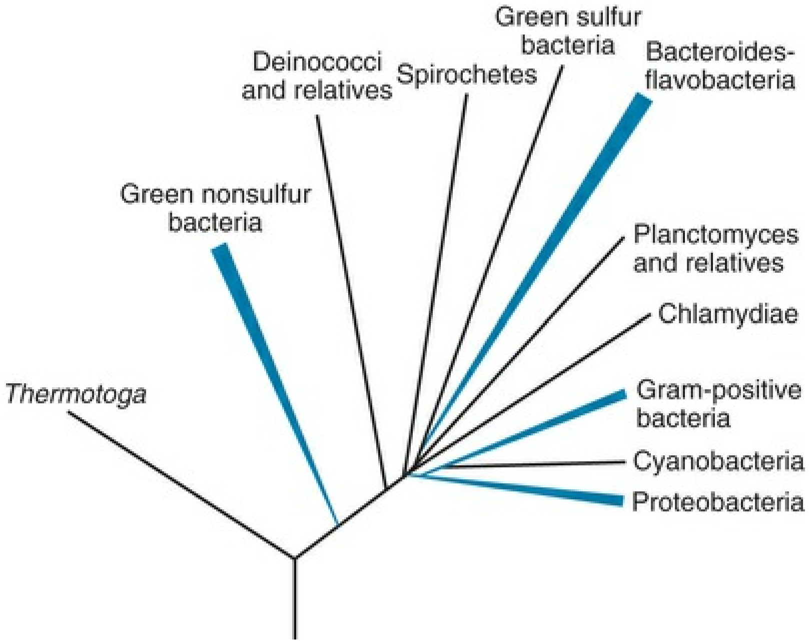

FIGURE 114.2 Phylogenic tree of the domain Bacteria based on comparison of 16S ribosomal RNA sequences. Divisions that contain human pathogens are denoted by boldface branches. (Redrawn from Relman DA. The identification of uncultured microbial pathogens. J Infect Dis 1993;168:1–8.)

Although 16S rRNA gene sequencing has clear strengths related to defining genetic relationships and classifying bacteria, use of this technique alone has limitations. For example, isolates that have divergent 16S rRNA gene sequences are consistently unrelated, but isolates that have almost identical 16S rRNA gene sequences may or may not belong to the same species, resulting in the need for another method to explore further whether isolates are sufficiently similar to be assigned to the same species. Consequently, multilocus sequence typing (MLST), which circumvents the potential effects of simple stochastic variation or recombination at a single locus, is becoming more common. MLST uses profiles of alleles at multiple (usually about seven) housekeeping gene sites to group isolates and determine relatedness between strains.[8,9] MLST has been especially useful in tracking the epidemiology of community-associated methicillin-resistant *Staphylococcus aureus* infections and the spread of virulent clones.[10,11]

Over the past decade, there has been a steady increase in the number of completely sequenced bacterial genomes, reflecting advances in sequencing technology. The availability of this information has led to the development of DNA microarrays and has allowed comparison of the whole genomes of individual isolates. Increasingly, whole genome information is used to assist with bacterial classification in general terms and in clinical settings.[12,13]

Beyond nucleic acid–based approaches to bacterial classification, whole-cell matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry has been demonstrated to be useful in classifying bacteria and comparing isolates for strain identity.[14,15] MALDI-TOF relies on the ionization of biomolecules, including whole proteins, and comparison of the resulting spectrum to a reference library. Identification by MALDI-TOF has the advantage of requiring significantly less time than other methods; samples can be analyzed directly from a colony on a plate with no special culturing needed.[16] However, the method is currently limited by the necessity of using proprietary rather than publicly available databases.[17]

Additional genetic and proteomic information continues to spur reclassifications.[18]

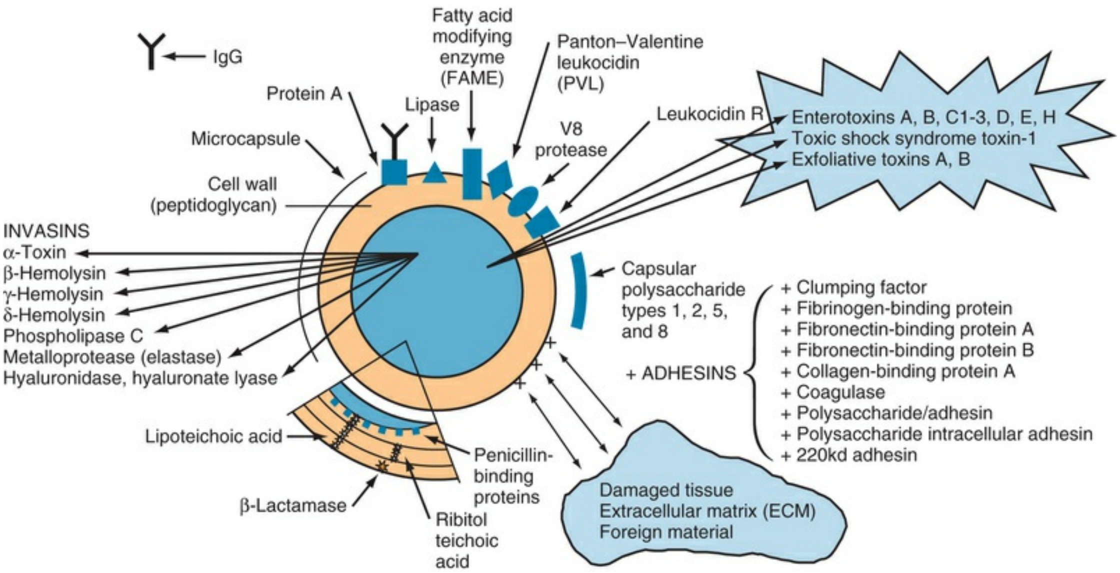
Staphylococcus aureus

Robert S. Daum

Staphylococcus aureus is the most virulent species of the genus *Staphylococcus* and the most common pathogen isolated among pediatric patients in North America. The pathogenicity of *S. aureus* reflects its ability to acquire and integrate accessory genetic elements that confer virulence. *S. aureus* is responsible for community- and healthcare-associated infections and toxin-mediated diseases, and it is a major cause of mortality. The species also is adept at evolving strategies to elude antimicrobial therapy, leading to limited therapeutic options.

Microbiology and Pathogenesis

Staphylococci are aerobic or facultatively anaerobic gram-positive cocci that can persist in distressed environments, such as acidic conditions, high sodium concentrations, and wide temperature variations. Staphylococci can survive on fomites, in dust, or on clothing for at least several days. The defining characteristics of *S. aureus* are the production of the extracellular enzyme coagulase and protein A (Fig. 115.1). Clinical manifestations of *S. aureus* infection can result from tissue invasion, hematogenous dissemination, or toxin release, which incite inflammatory cascades and tissue necrosis. Isolation of *S. aureus* from skin and mucosal sites also may represent asymptomatic colonization because the organism can be a commensal flora.



IgG
Protein A
Fatty acid modifying enzyme (FAME)
Lipase
Panton–Valentine leukocidin (PVL)
V8 protease
Leukocidin R

Capsule and Cell Wall

Many clinical *S. aureus* isolates have a polysaccharide capsule; 11 capsular serotypes have been described, but most experts believe that probably only 4 exist.[1] The high prevalence of two of the capsular polysaccharide types (5 and 8) in almost all collections of clinically important human and veterinary isolates suggests an important but uncertain role in pathogenesis. Bloodstream infection (BSI) has also been caused by unencapsulated organisms; for example, the so-called type 336 isolates and USA300.[2,3] Immunization with the type 5 and 8 polysaccharide conjugated to *Pseudomonas* exotoxoid A was the basis for two recent immunization trials, neither of which met primary end points.[4–6]

The cell wall of *S. aureus* is composed of peptidoglycan, capsular polysaccharide when present, ribitol teichoic acid, lipoteichoic acid, and many surface proteins, including protein A, which binds to the Fc region of the immunoglobulin G (IgG) molecule.[7] Binding of IgG antibody to the staphylococcal cell surface in this nonphysiologic manner is ineffectual and decreases the efficiency with which *S. aureus* is opsonized and phagocytosed.[8–10]

Surface Proteins

Many proteins found on the surface of *S. aureus* isolates have been implicated in pathogenesis. Adherence of *S. aureus* to mammalian extracellular matrix components is mediated by a family of adhesins, the microbial surface components that recognize adhesive matrix molecules (MSCRAMMs).[11] Coagulase is found on the bacterial cell surface and in its environment. Coagulase binds to host prothrombin and forms staphylothrombin, an enzyme that catalyzes the formation of fibrin from fibrinogen.[12] The A and B clumping factors are cell surface proteins that bind to fibrinogen, producing the typical clusters of staphylococci when mixed with plasma.[13] Coagulase and the clumping factors breach host defenses by causing localized clotting; the clumping factors also may aid adherence to traumatized skin, endothelial structures, and foreign surfaces. Recognition of the role of *S. aureus* clumping factors has prompted investigation into their potential use as vaccine antigens.[14]

Iron is an essential component of cytochromes and other redox proteins. A cell wall–bound system of iron acquisition and importation has been identified in *S. aureus* and is under investigation to define an apparently essential role in pathogenesis.[15] However, a trial of an iron-scavenging protein, ISDB, was terminated prematurely for lack of demonstrable benefit.[16]

Toxins

The virulence of *S. aureus* is due to a combination of variously elaborated proteins, including extracellular products (e.g., the α, β, γ, and δ hemolysins [also called toxins]), leukocidins, proteases, lipase, deoxyribonuclease, a fatty acid–modifying enzyme, and hyaluronidase.[17–23] The most extensively studied of the exotoxins is α-hemolysin, which causes hemolysis of erythrocytes, necrosis of the skin, and the release of cytokines and eicosanoids that can produce shock. *S. aureus* is lethal when injected into animals. *S.*

aureus mutants lacking α-hemolysin generally are less virulent,[24] although pathogenic *S. aureus* isolates that do not produce α-hemolysin have been identified. *S. aureus* β-hemolysin is a sphingomyelinase that can injure lipid-rich membranes; however, most human isolates do not express β-hemolysin. The high prevalence of γ-leukocidin genes in isolates that cause necrotizing skin infections suggests the importance of this toxin in causing dermonecrosis. *S. aureus* has several leukocidins, which are synergohymenotropic toxins that damage membranes of certain cells as a result of the concerted action of two elaborated, secreted proteins. The Panton-Valentine leukocidin (PVL) is a pore-forming cytotoxin,[25] and its toxic effect is said to result from the synergistic action of the proteins lukS-PV and lukF-PV.[26] PVL has been associated with severe inflammatory lesions, presumably through the activation of granulocytes.[27] PVL-producing strains have been associated with severe skin infections and lung infections,[28] specifically necrotizing pneumonia.[29] The importance of PVL in the pathogenesis of *S. aureus* infections, a controversial topic because of variation in the susceptibility of host species, has been clarified in human infections.[30–32]

S. aureus causes a variety of so-called toxin-mediated diseases, including staphylococcal scalded skin syndrome (SSSS), toxic shock syndrome (TSS), and staphylococcal food poisoning; all of these are caused by the action of exotoxins and enterotoxins. Exfoliative toxins A (ETA) and B (ETB) cleave the glycoprotein desmoglein 1, promoting the spread of *S. aureus* under the stratum corneum[33,34] and resulting in blistering of the superficial epidermis, which is characteristic of SSSS and bullous impetigo (Fig. 115.2). Toxic shock syndrome toxin-1 (TSST-1) and staphylococcal enterotoxins B (SEB) and C (SEC) have been implicated in most cases of TSS. These toxins have superantigen activity; that is, they stimulate T lymphocytes nonspecifically, resulting in cytokine release and clinical toxic shock. At a skin or mucosal port of entry TSST-1 can interfere with the release of inflammatory mediators locally, which may account for a surprisingly benign appearance at the local infective site. An expanding family of enterotoxins has been implicated in staphylococcal food poisoning, but the most frequently implicated molecule is enterotoxin A (SEA).

Genetic Basis and Regulation of Pathogenicity Factors and Antimicrobial Resistance

The whole genome of *S. aureus* has been sequenced many times. It has a circular chromosome of about 2.8 million base pairs.[35] Genes for many housekeeping functions are highly conserved. The genome also carries mobile genetic elements, such as plasmids, transposons, prophages, and pathogenicity islands, many of which encode virulence factors or determinants of antibiotic resistance. These factors represent a subset of a large class of accessory gene products (including surface proteins, exotoxins, and other enzymes) that provide one or more advantages in particular environments, although these accessory products are not required for growth and cell division.

S. aureus has evolved a remarkable network of regulatory mechanisms that control subsets of genes that are upregulated or downregulated under certain growth and environmental conditions. The most extensively studied is the *agr* locus with its two-component signal transduction system and its effector RNAIII molecule. The *agr* locus upregulates genes that encode capsular polysaccharides; α-δ toxins; two-component synergohymenotropic toxins; enterotoxins; exfoliatins; and proteases; it downregulates other genes, such as those that encode MSCRAMMs, other adhesins, and protein A. Other two-component signal transduction systems implicated in pathogenesis are *saeRS, srrAB, arlSR,* and *lytRS.* Protein systems that bind deoxyribonucleic acid (DNA), such as *sarA* and its regulatory homologues, also regulate virulence factors. Additionally, the σ-factor, σ^B, can combine with the ribonucleic acid (RNA) polymerase core enzyme to form a holoenzyme that can recognize promoter elements for at least 36 *S. aureus* genes involved in bacterial stress responses. Taken together, membrane sensing systems (e.g., *agr*) and DNA-binding regulatory systems afford *S. aureus* a versatile environmental response system and confer the capacity to respond to a myriad of environmental stimuli, such as high or low sodium chloride concentrations, subinhibitory concentrations of protein synthesis inhibitors, a low pH, or a condition in which essential nutrients (e.g., amino acids) are limited.

S. aureus can overcome environmental antibiotic pressure through the acquisition and transmission of resistance genes from other, usually less pathogenic, species and isolates of the same species. Resistance to β-lactam antibiotics (e.g., penicillins, cephalosporins, and carbapenems) is one example. The β-lactam antibiotics bind to *S. aureus* penicillin-binding proteins (PBPs), thereby inhibiting cell wall synthesis.

Resistance to penicillin was documented almost immediately after the medication's introduction into clinical practice in the 1940s. It is mediated by the elaboration of a β-lactamase, which is encoded by a transposon borne on a plasmid. Almost all clinical isolates of *S. aureus* can elaborate this enzyme, rendering antibiotics susceptible to β-lactamase hydrolysis clinically ineffective.

The development of β-lactamase–resistant semisynthetic penicillins temporarily overcame this widely prevalent clinical problem. However, some strains became resistant to semisynthetic compounds by acquiring *mecA,* a gene that elaborates PBP2a, a peptidoglycan-synthesizing enzyme that has decreased affinity for β-lactam antibiotics.[36,37] These resistant strains are called methicillin-resistant *Staphylococcus aureus* (MRSA) and are responsible for nosocomial outbreaks and for the current community-based MRSA epidemic. MRSA strains are resistant to all β-lactams except ceftaroline.

The *mecA* resistance gene is located on a mobile genetic element called the staphylococcal chromosome cassette *mec* (SCC*mec*),[38] which is present in all MRSA isolates, with occasional exceptions. SCC*mec* contains a *mec* complex, comprised of *mecA* and its variably present *mec1* and *mecR1* regulatory genes, and a *ccr* complex, comprised of genes that mediate insertion and excision of SCC*mec* from the genome. Insertion of SCC*mec* into the *S. aureus* genome is the genetic event that converts a methicillin-susceptible strain into a methicillin-resistant one. Currently 11 SCC*mec* elements have been sequenced or partially characterized. In the United States, mobile elements SCC*mec* types I to III generally are found in healthcare-associated MRSA (HA-MRSA) isolates, and SCC*mec* types IV and V generally are found in community-associated MRSA (CA-MRSA) isolates, although these distinctions are blurring.[39]

Although the mechanism of the movement of SCC*mec* elements from strain to strain is unknown, the large size of types I to III is believed to limit easy transfer of the elements. Types IV and V, however, are small and mobile. Types IV and V have been found in multiple *S. aureus* genetic backgrounds, which supports the hypothesis that they are readily transferred from strain to strain.[40–42] To date, types VI through XI have been identified in only a limited number of strains.

Epidemiology

Colonization

Humans and other mammals are the natural reservoirs for *S. aureus*. Asymptomatic colonization is frequent in humans, and traditionally the anterior nares were thought to be a predominant site. However, the skin, nails, pharynx, axillae, perineum, throat, rectum, and vagina are common sites of colonization. Colonization rates range from 25% to 50%; higher rates are found in children, in people with dermatologic conditions (e.g., eczema), in those who perform needle injections frequently (e.g., intravenous drug abusers), in those with indwelling intravascular devices (e.g., patients receiving dialysis), and in healthcare personnel (HCP). Even higher rates have been documented with the use of highly sensitive detection methods, leading some to speculate that colonization may be universal.[43] Although it has been held that most people are colonized intermittently (and fewer are persistently or rarely colonized[44]), scant explicit data are available. Traditionally, nasal *S. aureus* carriage has been a risk factor for developing an infection,[45–47] although most colonized individuals do not do so. CA-MRSA colonization affects more body sites, which correlates with an increased risk of infection.

Healthcare-Associated Infections

S. aureus can develop resistance to all classes of antimicrobial agents. The first MRSA strain was reported less than a year after the introduction of semisynthetic penicillins in the early 1960s, even though these penicillins were active against β-lactamase–producing, so-called methicillin-susceptible *S. aureus* (MSSA). Multidrug-resistant HA-MRSA strains spread worldwide in hospital settings. The National Healthcare Safety Network (NHSN) (formerly the National Nosocomial Infections Surveillance System), an agency of the Centers for Disease Control and Prevention (CDC), has reported *S. aureus* as a major pathogen of HAIs. In 2003 MRSA accounted for 64% of nosocomial *S. aureus* isolates in intensive care units (ICUs) in U.S. hospitals, an increase from 36% in 1992.[48] From January, 2006, to October, 2007, *S. aureus* was the second most common cause of HAIs, exceeded only by coagulase-negative staphylococci (CoNS).[49]

In pediatric ICUs in the U.S., *S. aureus* is the major nosocomial pathogen in a variety of clinical situations; it accounts for 9% of HA bloodstream infections (HA-BSIs), 17% of cases of HA pneumonia, and 20% of surgical site infections.[50] Current patterns of HA-MRSA isolates reveal decreasing rates of isolation[51] and decreasing resistance to non–β-lactam antibiotics; this suggests a shift in nosocomial MRSA epidemiology, probably reflecting the movement of “biologically fit” CA-MRSA isolates into the hospital.[40,52]

In recent years MSSA has become a healthcare-associated pathogen, predominantly over MRSA in some settings, but more frequently associated with BSI and the requirement for intensive care.

Community-Associated MRSA Infections

Prevalent MRSA infection outside the healthcare setting was first reported in 1982 in Detroit, Michigan, among intravenous (IV) drug users.[53] This and subsequent reports of CA-MRSA were associated with risk factors for infection similar to those for HA-MRSA, including IV drug administration, recent hospitalization or surgery, presence of indwelling catheters or devices, dialysis, or residence in a longterm care facility.[54–57] In the late 1990s CA-MRSA infections emerged; these infections occurred mostly in children with no identifiable predisposing MRSA risk factors,[58–62] and they commonly resulted in skin and soft tissue infections (SSTIs). Some serious infections required hospitalization or were fatal.[63] The number and geographic distribution of CA-MRSA infections grew substantially. Strong evidence supports the de novo rise of MRSA in the community, rather than movement of HA-MRSA into the community.[64,65]

A CA-MRSA infection can be defined as one that occurs in an outpatient or that develops within 72 hours of admission to the hospital in a patient without any of the factors used to define risk for HA-MRSA: recent hospitalization or surgery, prolonged antibiotic therapy, underlying chronic disease, indwelling catheter or other device, healthcare contact, or residence in a longterm facility.[66] Molecular definitions also have been used to distinguish HA-MRSA from CA-MRSA strains.[67] Outbreaks of CA-MRSA infections have been reported in group childcare settings,[57,68] sports teams,[69,70] correctional facilities,[71,72] and military units,[73,74] which suggests that close contact and suboptimal hygiene practices play a role in the spread of infection.

CA-MRSA isolates also can be distinguished from HA-MRSA by their lack of multidrug resistance. Most CA-MRSA isolates are susceptible to clindamycin, trimethoprim-sulfamethoxazole (TMP-SMX), and doxycycline, whereas HA-MRSA isolates usually are resistant to these agents. Multilocus sequence typing, SCC*mec* typing, and pulsed-field gel electrophoresis have elucidated important differences between HA-MRSA and CA-MRSA isolates. In the U.S., HA-MRSA usually contain SCC*mec* type II and genes that mediate resistance to several non–β-lactam antibiotics. In contrast, CA-MRSA isolates usually contain SCC*mec* type IV or type

V and lack non–β-lactam antibiotic resistance genes.[59] Even among CA-MRSA isolates, however, determinants of non–β-lactam agent resistance can be found elsewhere in the cell, such as on plasmids or in the chromosome. For example, erythromycin resistance is common among both HA-MRSA and CA-MRSA strains and can be mediated by a variety of phenotypic and genetic mechanisms. When the *erm* gene that commonly mediates erythromycin resistance is present, the constitutive or inducible MLS_B phenotype (discussed later in the chapter) is conferred.[75,76]

Another difference between CA-MRSA and HA-MRSA isolates is their repertoire of toxin genes.[77] The most striking examples are the *lukS-PV* and *lukF-PV* genes that encode for PVL and are transferred from strain to strain by an as yet unknown mechanism.[78] These toxin genes have been associated with MSSA and MRSA strains that cause SSTIs, necrotizing pneumonia, and empyema.[79–81] More severe infections, such as severe sepsis, thrombosis, and thromboembolism, also are caused by isolates containing the PVL genes.[30] Interestingly, although SCC*mec* IV or SCC*mec* V and PVL together seem to confer a selective advantage for spread (i.e., transmission and colonization) and pathogenicity (i.e., excess rate of infection per colonized individual), the genes encoding PVL are transferred separately from the SCC*mec* element. Most circulating CA-MRSA organisms in the U.S. belong to a genetic lineage called USA 300 (from a nomenclature scheme based on pulsed-field gel electrophoretic pattern). These organisms contain an island of foreign DNA called the arginine catabolic mobile element (ACME)–encoded *arc* cluster. The role of ACME is the subject of controversy, but it is believed to confer an improved survival advantage on skin and spermidine susceptibility.[82–84]

Vancomycin-Intermediate *S. aureus* and Vancomycin-Resistant *S. aureus* Infections

S. aureus isolates with decreased susceptibility to vancomycin also emerged in the late 1990s. These vancomycin-intermediate *S. aureus* (VISA) strains, defined as having a minimal inhibitory concentration (MIC) of vancomycin greater than 2 μg/mL, typically have been isolated from patients with underlying medical conditions in whom vancomycin therapy has failed[85,86]; these strains usually also are resistant to teicoplanin (a glycopeptide not licensed in the U.S.). Therefore, the term glycopeptide-intermediately susceptible *S. aureus* (GISA) may be more appropriate. In 2002 the first high-level vancomycin-resistant *S. aureus* (VRSA) strain was reported (MIC of vancomycin >16 μg/mL); this isolate apparently acquired the *vanA* vancomycin resistance genes from *Enterococcus* organisms. To date, 13 VRSA isolates have been reported in the U.S., and all strains evaluated have carried the *vanA* gene.[87–89]

Clinical Manifestations

Skin and Soft Tissue Infections

Impetigo

S. aureus is a major cause of several infections of the skin and its appendages. The most superficial is impetigo, which begins as a small, tender, erythematous papule. Often the integument has been interrupted, such as by an insect bite, a varicella vesicle, eczema, or a minor abrasion from trauma. Bullous impetigo is a specific *S. aureus* infection in which transparent bullae rupture easily, exposing a moist base surrounded by a thin rim of scale (Fig. 115.3). Bullous impetigo is mediated by the production of ETA and ETB.[90,91]

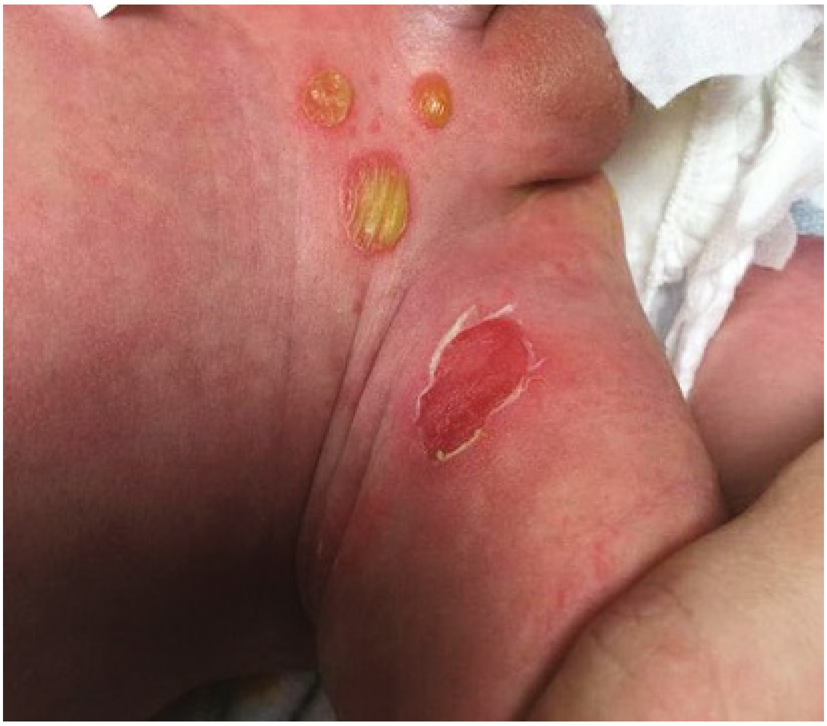

FIGURE 115.3 Bullous impetigo in a neonate. (Courtesy of J.H. Brien©.)

Several studies have demonstrated the superiority of topical or systemic antibiotics over simple cleansing for the treatment of impetigo. For uncomplicated singular sites of impetigo in children outside the neonatal period, topical mupirocin can be appropriate. Mupirocin ointment should be applied 3 times daily for 7 to 10 days. Retapamulin recently was licensed for topical therapy for children 9 months of age or older who have impetigo caused by *Streptococcus pyogenes* or MSSA (but not MRSA).[92] This drug's place in the therapeutic armamentarium has yet to be determined. Many experts prefer systemic antimicrobial therapy for the treatment of bullous impetigo.[93]

Oral or parenteral antimicrobial therapy should be considered if the impetigo is widespread. Because of the high prevalence of MRSA, a culture should be performed before the initiation of systemic therapy in most patients. Neonates with minor bullous impetigo (frequently near the umbilicus) who are afebrile and well sometimes can be managed with oral empiric systemic antimicrobial therapy with an agent active against MRSA.

Abscess

S. aureus commonly causes superficial abscesses of the skin. Moist and hairy skin is particularly susceptible to furuncles, boils, folliculitis, and hidradenitis. When the lesion is associated with a hair shaft, the term furuncle is often used (see Fig. 68.6). Rupture yields a purulent discharge. A carbuncle is a larger lesion formed by the coalescence of furuncles. With most small skin abscesses the symptoms pain and erythema are local, although fever can be present. Systemic signs can accompany larger lesions. In the neonate a skin abscess or boil can progress rapidly to BSI and clinical sepsis.

S. aureus is the leading cause of breast abscess in infants, which commonly occurs within the first 3 weeks of life, when the breasts are enlarged physiologically (Fig. 115.4) The abscess usually is unilateral and accompanied by erythema and induration. Occasionally fever, leukocytosis, or BSI can occur. Isolation of the pathogen from the abscess's discharge aids management.[94]

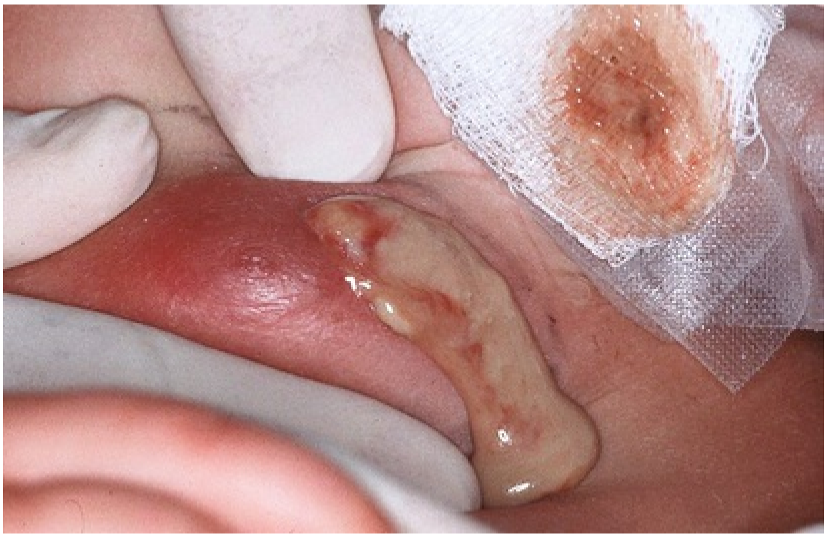

FIGURE 115.4 Abscess and cellulitis due to community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA). (Courtesy of J. H. Brien©.)

Local cleansing and incision and drainage are essential components of the management of abscesses.[95,96] Sometimes small abscesses (<5 cm) can be treated without systemic antimicrobial therapy[95]; however, in a randomized, placebo-controlled trial, TMP-SMX had a higher clinical cure rate.[97] Neonates with skin abscesses and infants with a breast abscess should be treated. Systemic antibiotic treatment also is required for any patient with severe or extensive disease, rapid progression of associated cellulitis, systemic illness, associated comorbidity or immunosuppression, abscess in an area difficult to drain (e.g., face, genitalia, hand), or associated phlebitis.[98]

Any abscess can heal with scarring. Some patients may suffer from recurrent furunculosis, which can be difficult to manage. Systemic and topical antimicrobial agents, along with careful hand and nail hygiene, may help reduce recurrences.

Recurring MRSA SSTIs are common and pose a management challenge. Underlying skin conditions (e.g., eczema, diaper dermatitis) should be managed aggressively. Attempts to decolonize a patient with nasal mupirocin or applications of an antiseptic (e.g., chlorhexidine) often are unsuccessful; in addition, the right time to attempt such decolonization is unclear. Consideration of congenital or acquired immunodeficiency may be warranted in patients with recurrent disease, especially if the response to therapy is slow or healing occurs with remarkable scarring.[99]

Cellulitis

Cellulitis is an infection of the subcutaneous tissues and the dermis that manifests as an area of erythema, warmth, edema, and tenderness. *S. aureus* is a major cause of the infection in all age groups and at all clinical sites. If systemic signs are present, a blood culture should be performed before antimicrobial therapy is started. When present, purulent material should be cultured. Culturing an aspirate or biopsy specimen from a patient with nonpurulent cellulitis can yield the infecting bacterium.[100]

Treatment involves oral or parenteral antimicrobial therapy, depending on the extent of disease and whether systemic signs or toxicity is present.

Wound Infection

The likelihood of a postoperative or posttraumatic wound infection increases with the use of sutures, especially in poorly vascularized tissues. Measures that often can prevent infections include frequent dressing changes, meticulous daily wound care, and strict handwashing. *S. aureus* wound infections generally are recognized within a few days after trauma or surgery; inflammation is a local sign, and constitutional signs of illness may be present. The exudate often is cloudy, hemorrhagic, and notably odorless. Extension of a wound infection into deeper tissues can occur, resulting in cellulitis, lymphadenitis, lymphangitis, or necrotizing fasciitis. Bursitis usually is the complication of a contiguous skin infection, frequently with trauma, and must be differentiated from pyogenic arthritis.

Treatment of a wound infection includes exploration of the wound, drainage, removal of any foreign material, and optimization of skin hygiene. Topical or systemic antimicrobial therapy may be a useful adjunct for mild infections. Parenteral antimicrobial therapy should be considered for clinically serious or extensive infections and for wound infections on the head and neck.

Ocular Infections

S. aureus is an important cause of purulent conjunctivitis. The causative organism can be visualized by Gram stain or isolated from purulent discharge. Conjunctivitis usually resolves without treatment, although topical ophthalmic antimicrobial agents frequently are used. *S. aureus* is the most frequently recognized cause of a stye or a hordeolum, an infection of the sebaceous gland or the eyelash follicle, respectively. Use of a topical antimicrobial agent may prevent the spread of infection to adjacent hair follicles, but frequent application of warm compresses usually suffices for treatment.[101]

Preseptal (periorbital) cellulitis can result from extension of sinusitis or from autoinoculation of skin flora after a break in the skin due to local trauma, an insect bite, an abscess, or impetigo.[102] (Fig. 115.5). *S. aureus* is the leading cause of skin lesion–related preseptal cellulitis. Because of the elasticity and thinness of the skin in and around the eyelid, the clinical presentation can be dramatic, with a rapid onset of lid swelling, erythema, and tenderness.[103] Low-grade fever and leukocytosis can be present, although typically the child does not appear systemically ill. Visual acuity is not affected, and movement of the globe is not painful or limited. Treatment of preseptal cellulitis usually is initiated parenterally; oral therapy can be substituted after a clinical response has been demonstrated.

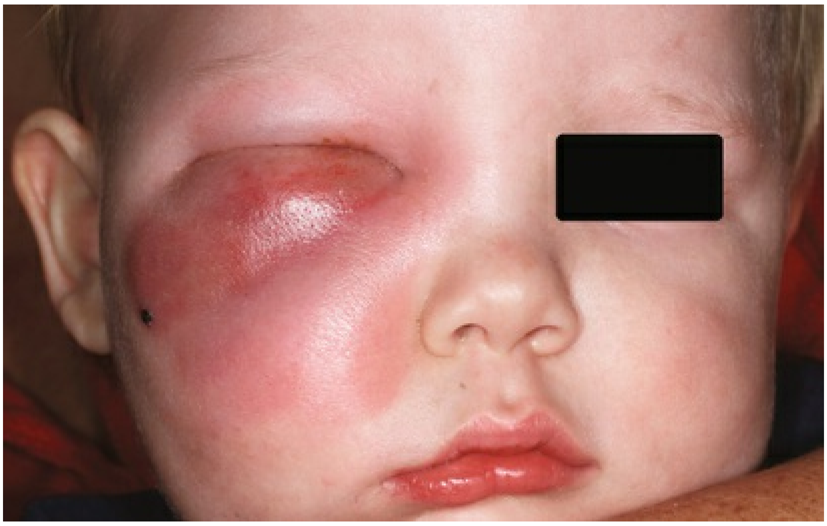

FIGURE 115.5 Preseptal cellulitis due to MRSA infection after minor trauma. (Courtesy of J.H. Brien©.)

S. aureus is presumed to be the leading cause of orbital (postseptal) cellulitis after surgical or accidental trauma to the orbit, and it can be responsible for orbital cellulitis that complicates sinusitis.[104] Patients or parents note a red, swollen "eye"; the physical examination reveals one or more of the following: decreased or painful movement of the globe, impaired visual acuity, chemosis, or proptosis.[103] Complicating cavernous sinus thrombosis should be suspected if the patient has abnormal neurologic findings.[105] Treatment requires confirmation of the pathogen and antimicrobial susceptibility. CT helps distinguish between orbital phlegmon, subperiosteal abscess, and orbital abscess; staphylococci are more often associated with abscesses. These diagnoses mandate assessment for surgical drainage in addition to IV antibiotics.[106] An extended course of antimicrobial therapy is given parenterally.

S. aureus endophthalmitis is an uncommon infection in children and usually follows ocular surgery or penetrating trauma to the globe.[107] Symptoms include blurred vision, redness, pain, lid swelling, and the presence of a hypopyon. Systemic signs or fever and lethargy often are present. Treatment includes antibiotics, both given parenterally and instilled directly into the vitreal cavity, and vitrectomy. Visual outcomes are poor.[108]

Invasive Infections

Osteomyelitis

S. aureus is the major cause of hematogenous osteomyelitis, accounting for up to 90% of cases. The metaphyses of long, tubular bones are affected most frequently, although infection can occur in any bone.[109–112] Previous minor trauma may predispose a person to infection, probably as the result of subclinical minor vascular injury or because a small area of bony necrosis acts as a nidus for seeding during what otherwise would have been asymptomatic bacteremia.[113] The classic clinical picture includes fever and point tenderness over the affected area of bone (usually at the metaphysis), decreased range of motion, and minor local signs of inflammation. Infants and toddlers can manifest only irritability, limp, or refusal to bear weight. Diagnosis requires a high degree of suspicion. Symptoms usually are present 1 week or less before they come to medical attention, but occasionally they are present for several weeks before recognition.[114]

Evaluation should include a blood culture because BSI is detectable in about 50% of patients.[115] At the time of clinical presentation the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level usually are elevated, although normal values can be seen, particularly among neonates or patients with sickle cell disease, distal digital infection, or subacute cases (e.g., Brodie abscess). Other acute phase reactants (e.g., leukocyte count) may be normal.[116] A radiograph of the affected bone is likely to have a normal appearance in the first days after the onset of symptoms, or it may show only deep soft tissue swelling adjacent to the bony metaphysis; periosteal elevation or lucencies within the bone typically are not apparent until 10 to 21 days after the onset of infection. A technetium-99 methylene phosphonate scan, performed in three phases, identifies increases in regional perfusion and tracer uptake by inflamed bone. Scintigraphy is especially useful for detecting multifocal infection. Although scintigraphy is sensitive, the results can be normal in neonates and patients with sickle cell disease with osteomyelitis. MRI is the most accurate diagnostic test, and it also can identify critical fascial and deep muscle phlegmon and abscess.[117]

Establishing the causative organism by needle aspiration or biopsy of the bone is important, especially if blood cultures are negative. Surgical intervention beyond a diagnostic needle aspiration usually is not required for simple acute osteomyelitis, but it can be indicated urgently if extensive subperiosteal or soft tissue infection or ischemic compartment syndrome is present, and it must be repeated frequently. Surgery often is required for chronic infection to remove sequestra and to debride affected bone.

IV antibiotics should be initiated and subsequently modified according to microbiology test results. Most experts recommend a course of antimicrobial therapy extending up to 4 weeks or longer for *S. aureus* osteomyelitis, with parenteral therapy used initially. Deep vein thrombosis adjacent to the bony site of infection and septic thromboembolism increasingly have become recognized as complications of *S. aureus* osteomyelitis, especially when they are caused by CA-MRSA or PVL-positive MSSA. These conditions usually develop in the proximal long bones and vertebrae.[118] The total duration of the therapy and the transition to oral therapy is individualized, depending on the extent of infection, susceptibility test results, the clinical setting and course.[114,119,120] One study has shown that a total course of therapy of 3 weeks to be noninferior,[120] and another study has shown that early transition to oral therapy also is effective, even when CA-MRSA is the cause.[121]

Techniques for monitoring the therapeutic response vary, and few explicit data are available. Most experts use a rapid fall in the CRP level as evidence of an appropriate antibiotic choice, and an eventual fall in the ESR as a guide to an adequate duration of therapy. In general, serial imaging of the infected bone does not provide useful information about the duration of therapy.

S. aureus can cause osteomyelitis secondary to an adjacent deep soft tissue focus; by concurrent direct inoculation; or by contiguous spread, such as through an accidental puncture wound of the foot or the patella, a bite, trauma, an infected paronychia, or a surgical procedure.[122] Osteomyelitis that develops after a puncture wound frequently is called osteochondritis, partly to remind clinicians of the clinical and pathophysiologic features that distinguish it from hematogenous osteomyelitis. Symptoms and signs of acute hematogenous osteomyelitis usually are absent, although many patients have localized pain, fever, and erythema. The blood typically is sterile, and the CRP level can be minimally increased or normal. Surgical debridement is an important component of the therapeutic strategy in nonhematogenous osteomyelitis/osteochondritis syndromes; antimicrobial therapy is adjunctive. The optimal duration of antimicrobial therapy for osteochondritis is unclear, but it frequently can be short (e.g., 7 to 14 days) after adequate surgical debridement in selected cases.[114]

Diskitis

Diskitis, or inflammation of an intervertebral disk, is uncommon and occurs primarily in children younger than 5 years of age. Diskitis may be difficult to distinguish from vertebral osteomyelitis, and the two entities probably have a similar pathogenesis (see chapters 76 and 78). Children with diskitis usually are not febrile or ill, but they refuse to walk, limp or, in older children, have back pain. MRI helps distinguish diskitis from vertebral osteomyelitis. *S. aureus* is the most frequently identified organism in both entities, although specimens are collected more frequently and are positive more frequently in patients with vertebral osteomyelitis. Diskitis may resolve spontaneously without antimicrobial therapy; vertebral osteomyelitis does not.

Diskitis without adjacent vertebral involvement sometimes can be managed with observation alone. If the adjacent vertebrae are involved, vertebral osteomyelitis cannot be excluded, and these patients should receive a course of antimicrobial therapy appropriate for osteomyelitis. Follow-up imaging studies are appropriate in this circumstance.[123]

Pyogenic Arthritis

Hematogenous seeding of the synovium during *S. aureus* BSI is the most common pathogenesis of infectious arthritis in children. Pyogenic arthritis usually is heralded by warmth, tenderness, erythema, and limited range of motion of the involved joint. Manifestations of a hip infection can be more subtle because of the depth of tissue surrounding the joint. In infants a subtle increase in resistance to movement or pain with movement may be the only clue. An imaging study (e.g., ultrasonography) is valuable.[124] Infants with osteomyelitis of the femur or humerus especially are prone to pyogenic arthritis of the contiguous joint due to the vascular and capsular anatomy in this region at this age[125] (see Fig. 76.4).

If pyogenic arthritis is suspected, blood culture and aspiration of joint fluid are performed urgently; the hip usually is drained surgically. The fluid is evaluated by Gram stain and culture, total and differential cell counts, and glucose and protein levels. In occasional cases of *S. aureus* arthritis, bacteria visualized on Gram stain are not isolated in culture because of the bacteriostatic nature of synovial fluid or previous antimicrobial therapy.

Treatment consists of surgical drainage and antimicrobial therapy. Antimicrobial therapy should be initiated when clinical suspicion is high and is continued for at least 3 weeks. Multiple aspiration procedures may be necessary. Open surgical drainage is used when serial aspiration does not produce a rapid response; as initial management when the hip or shoulder joint is affected; or when establishing effective drainage by simple aspiration is technically difficult and the risk of longterm complications is high.[114] A poor outcome is associated with delay of appropriate management and concomitant osteomyelitis.[126]

Abscesses of Muscle and Viscera

S. aureus is the most common cause of pyomyositis (including iliopsoas and obturator internus abscess) and liver abscess, and it is an important cause of renal, perinephric, splenic, and pancreatic abscesses. These are all complications of BSI, which may have been asymptomatic; the patient may come to medical attention because of symptoms related to the focal infection or for fever of unknown origin (FUO) or associated with severe sepsis. Necrotizing fasciitis, especially due to CA-MRSA, usually occurs as a complication of skin infection but also can occur after seeding of a deep site during BSI (see Fig. 75.2). Pyomyositis usually manifests with fever and an insidious or acute onset of cramping muscle pain, tenderness and, especially, induration of a large muscle group, such as those near the buttock, thigh, or hip. An obturator internus abscess can cause a painful limp, pelvic girdle pain, or refusal to walk. An iliopsoas abscess can cause predominantly flank pain and tenderness. A visceral abscess and nephric abscesses are most likely to manifest as FUO, possibly accompanied by nonspecific abdominal or flank symptoms. A blood culture is positive in fewer than one half of cases that present because of FUO or localized complaints.

CT or MRI is highly likely to identify abnormalities. Management usually entails surgical decompression, debridement and drainage, and prolonged parenteral antibiotic therapy. Multiple, small visceral abscesses frequently can be treated with antibiotic therapy alone if the pathogen is identified and susceptibility test results are available. Necrotizing fasciitis is a surgical emergency and requires decompression and debridement of the involved tissue and antimicrobial therapy.

Upper Respiratory Tract Infections

Head and Neck Infections

S. aureus is an infrequent cause of acute otitis media or sinusitis, but it should be considered in a child who fails multiple courses of empiric, oral antimicrobial therapy and in chronic or complicated disease. Both MSSA and MRSA increasingly have been isolated in cases of otorrhea that develops after tympanostomy tube insertion, and as complications of paranasal sinusitis.[104,127,128]

S. aureus is the leading cause of nasolacrimal duct abscess, suppurative parotitis, abscess of a lymph node below the angle of the jaw in very young infants (Fig. 115.6), and retropharyngeal abscess in children younger than 3 years of age (see Fig. 28.1). Infection occurs presumably after nasopharyngeal or oropharyngeal colonization, sometimes in association with a viral infection. In older children and adolescents *S. aureus* is the leading cause of peritonsillar and parapharyngeal abscess associated with recurrent pharyngeal infections and suppurative cervical lymphadenitis.

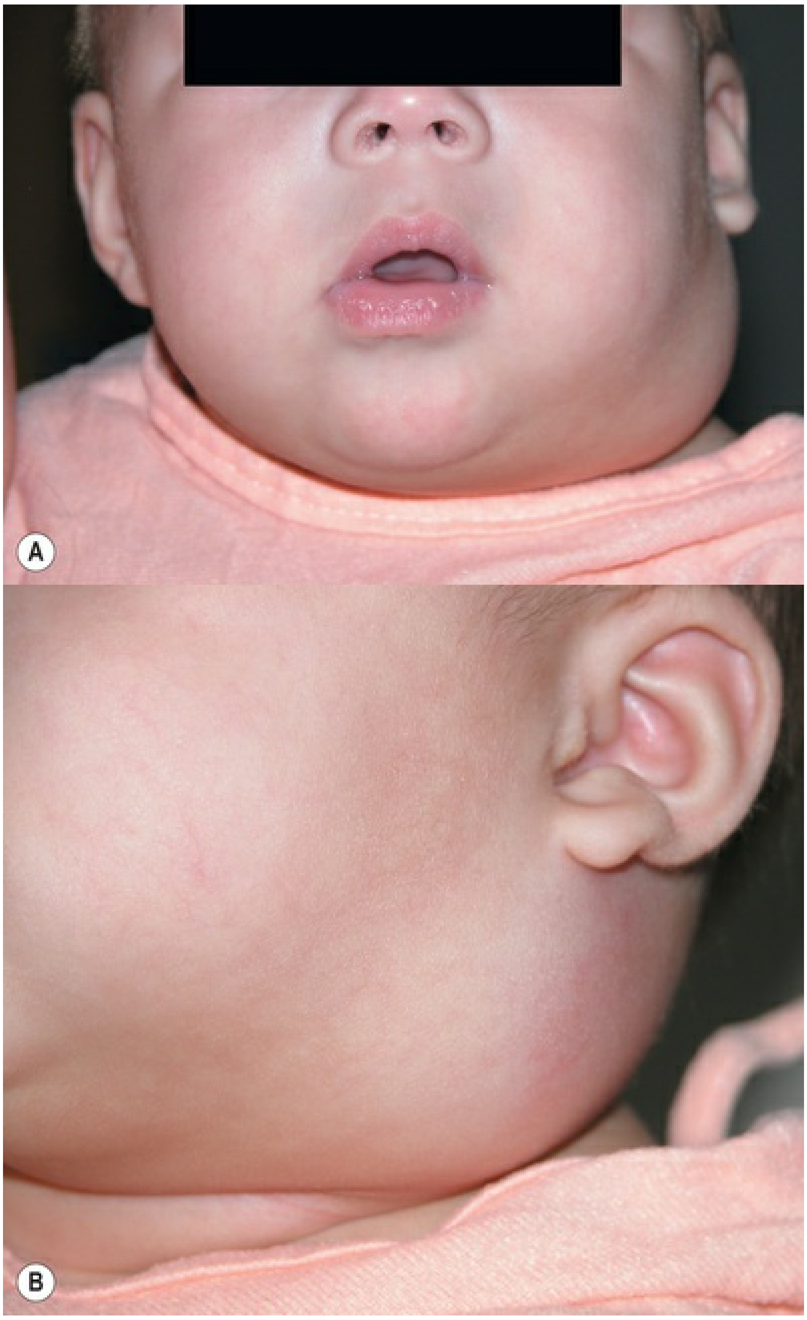

FIGURE 115.6 Two-month-old infant with necrotizing lymphadenitis due to MSSA. The infant had no intraoral, skin, or middle-ear abnormality. Note the location of the mass (A and B) and elevation of the earlobe (A). (Courtesy of J.H. Brien©.)

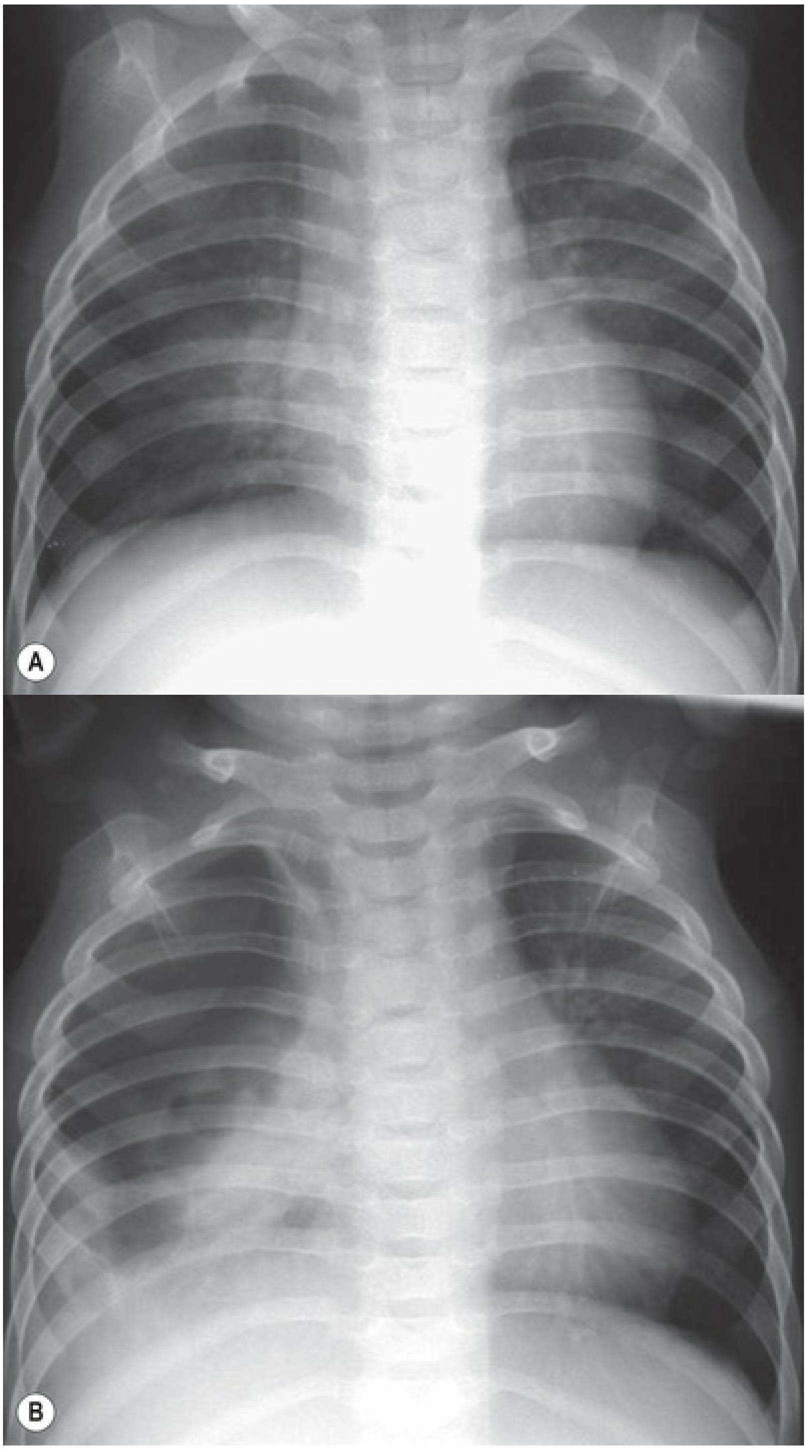
Tracheitis

Bacterial tracheitis caused by *S. aureus* can occur in an airway inflamed by a viral process or injured by medical manipulation. Affected patients manifest hoarseness and stridor (if the larynx is involved concomitantly) and can deteriorate suddenly, showing respiratory distress and s high temperature. The diagnosis can be suspected by the results of imaging studies and is confirmed by direct visualization of thick, purulent secretions in the trachea and subglottic edema, along with a positive Gram stain of secretions and recovery of *S. aureus* upon culture. Management includes establishment of an artificial airway and IV antibiotic therapy[129] (see Chapter 28).

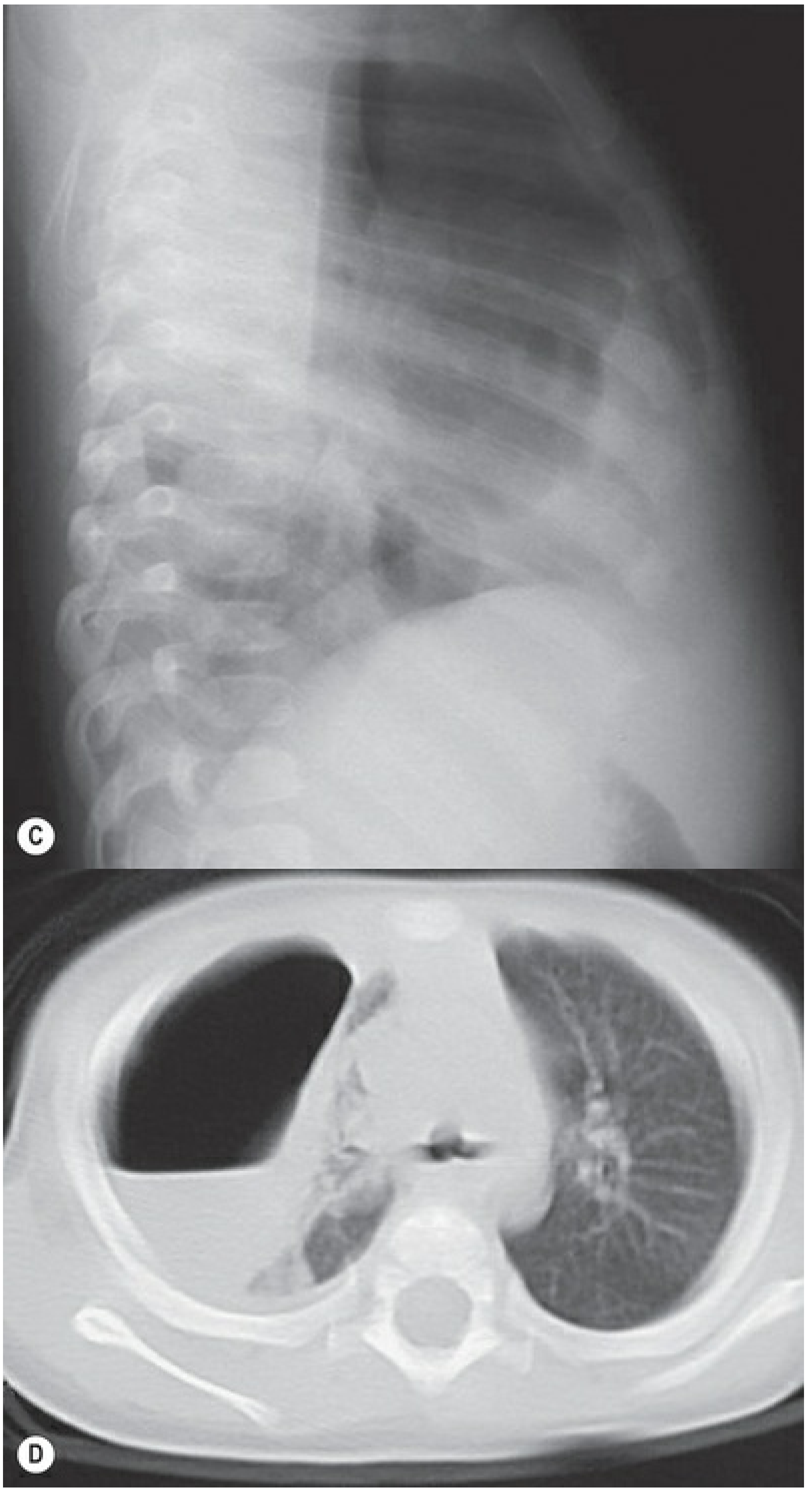
Lower Respiratory Tract Infections

Pneumonia

S. aureus can cause rapidly progressive pneumonia after inhalation of the organism or seeding of the lungs during BSI. Clinical features include fever, cough, grunting, and tachypnea, which can evolve into rapidly progressive and severe respiratory distress. A chest radiograph demonstrates multiple, patchy alveolar infiltrates that tend to coalesce to form large consolidations (Fig. 115.7). Pleural effusion and empyema accompany about 90% of pulmonary infections; spontaneous pneumothorax occurs in 25% to 50%. A pneumatocele (an air- or fluid-filled cavitation resulting from dissolution of intra-alveolar septa) occurs in more than 50% of cases. Most cases occur in previously healthy children, although predisposing factors (e.g., young age [younger than 1 year], chronic lung disease, immunosuppression, and presence of a foreign body or skin infection) may increase the likelihood of *S. aureus* pneumonia. A seasonal peak in *S. aureus* pneumonia is associated with viral respiratory tract infections such as influenza, presumably because viral illness transiently alters pulmonary defense mechanisms.[130]



A
B



C
D

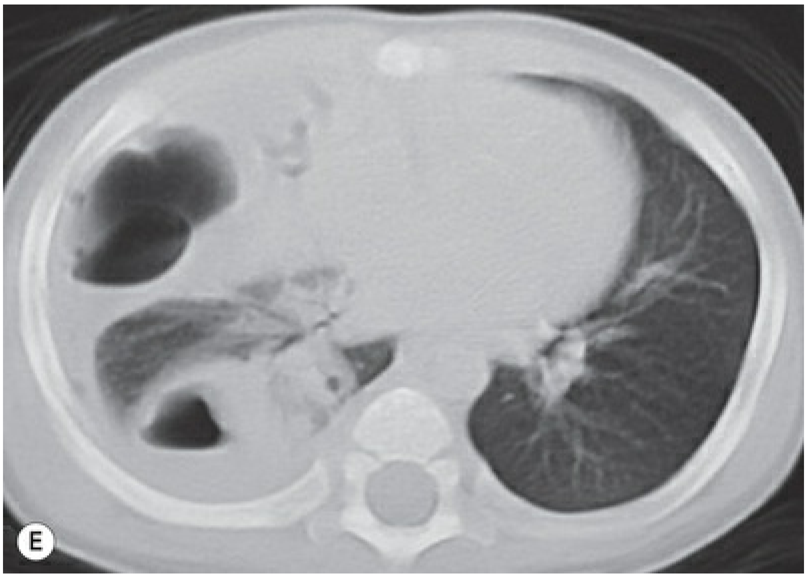


FIGURE 115.7 Progressive MRSA pneumonia with pneumatoceles in a previously healthy 9-month-old boy. Chest radiographic findings spanning 4 days showed a perihilar right lower lobe infiltrate (A) progressing to a worsening infiltrate and large hydropneumothorax with mediastinal shift (B and C) despite appropriate therapy. Axial CT of the chest without contrast (lung windows) showed partial loculation of hydropneumothorax, multilobar consolidation, pneumatoceles, and atelectasis (D and E). Video-assisted thoracoscopic surgery (VATS) was performed, and a chest tube was placed for 3 days. MRSA was isolated from pleural fluid. After 2 weeks of clindamycin therapy the chest radiograph had only minor abnormalities. (Courtesy of S.S. Long.)

S. aureus necrotizing community-acquired pneumonia (CAP) has increased dramatically in immunocompetent children. It can be caused by both MSSA and MRSA strains, which usually contain the PVL genes.[28,131–134] Leukopenia, and rapidly progressive unilateral or bilateral diffuse parenchymal pulmonary infiltrates are typical.[29] Severe sepsis syndrome can be present and has a high fatality rate. Histologic findings at autopsy reveal dense *S. aureus* with necrosis extending from the tracheobronchial epithelium to the congested and hemorrhagic parenchyma of the lung[29,80] (Fig. 115.8).

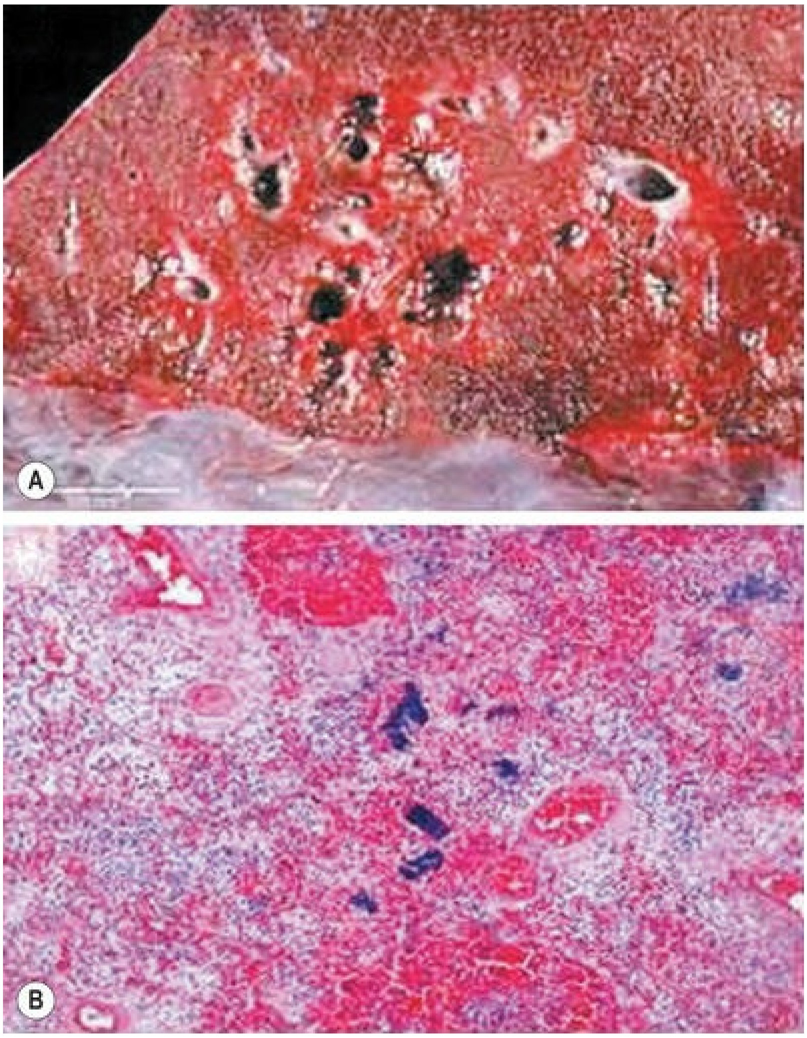

FIGURE 115.8 Pathologic findings from a patient with fatal necrotizing pneumonia due to *S. aureus* show a gross specimen of lung with microabscesses (A), and the histologic appearance of a section of lung with *S. aureus* colonies and hemorrhage (B). (Hematoxylin-eosin stain.) (From Adem PV, et al. *Staphylococcus aureus* sepsis and the Waterhouse-Friderichsen syndrome in children. N Engl J Med 2005;353:1245–1251.)

A high index of suspicion for *S. aureus* is critical in evaluating possible cases and aggressively treating them with empiric therapy active against MRSA and MSSA. The diagnosis is confirmed by recovery of the organism from pleural fluid, blood, or tracheobronchial aspirate. The duration of parenteral antimicrobial therapy depends on the clinical course. When compared with nonoperative treatment, early intervention for empyema with video-assisted thoracoscopic surgery (VATS) or open surgical debridement reduces mortality and the duration of antimicrobial therapy.[135]

Lung Abscess

Lung abscess can result as a complication of aspiration of infected material or a foreign body, can develop during pneumonia, or can result from hematogenous seeding during *S. aureus* BSI or septic thrombophlebitis. When bacteriology is proved as the mechanism of infection in children with aspiration, *S. aureus* can be recovered with or without facultative and anaerobic oral bacteria.[136,137]

Clinical features of *S. aureus* lung abscess include fever, cough, chest pain, dyspnea, anorexia, and weight loss.[136] CT helps determine the extent of disease and aids in following abscess resolution. Despite a dramatic appearance on radiographs, lung abscesses uncomplicated by pleural empyema usually can be treated adequately with IV antimicrobial therapy alone, as evidenced by resolution seen on follow-up chest radiographs.[138] Surgical drainage occasionally is required.[139] In these situations percutaneous drainage is a well-established technique.[140–142]

Cardiovascular Infections

Endocarditis

S. aureus is the most common cause of infective endocarditis (IE).[143] IE occurs more frequently in patients with congenital heart disease, whether surgically repaired or not, but can follow *S. aureus* BSI in any patient; or, it can be associated with device-associated persistent BSI.[144] Children whose cardiac lesions cause high-velocity blood flow and those with prosthetic valves or patches have an increased risk of developing *S. aureus* IE.[145,146]

Fever, a new or changed heart murmur, and continuous BSI are the hallmarks of IE. The presentation can be indolent or acute; common complaints include myalgia, arthralgia, general malaise, weight loss, and anorexia. Clinical progression can be rapid, with associated lethargy and cardiac failure, particularly when the aortic valve is involved. Right-sided endocarditis can be the source of emboli to the lungs, causing lung abscesses. Small vessel embolic phenomena, such as petechiae, splinter and conjunctival hemorrhages, and Janeway lesions, rarely manifest in children.[145]

The diagnosis is straightforward when echocardiography demonstrates a vegetation or abscess. However, this evidence may be lacking in children. A negative finding on a transthoracic or transesophageal echocardiogram does not exclude IE.[147,148] The modified Duke criteria have been used to identify children with IE based on major and minor clinical criteria (see Chapter 37).

Treatment requires 4 to 6 weeks of high-dose bactericidal antimicrobial therapy, administered intravenously, because of the relatively avascular nature of valves, the high organism load, and the decreased ability of polymorphonuclear leukocytes to function in endocarditis lesions. Guidelines for the treatment of *S. aureus* endocarditis, including consideration of combination therapy with aminoglycosides, can be found in Baltimore and colleagues[149] and Chapter 37. Fever may persist for about 1 week after the start of antimicrobial therapy.[150] Sustained bacteremia that spans several days in usual. Serial blood cultures should be obtained until sterility is demonstrated. Occasionally, surgical intervention is necessary, particularly when embolic phenomena to major organs, intractable cardiac failure, or aortic insufficiency is documented, or when BSI persists despite appropriate antimicrobial therapy, particularly when a prosthetic valve or other foreign material is involved. Prosthetic valve endocarditis caused by *S. aureus* poses a risk of mortality.[151,152]

Close follow-up should be maintained after therapy has been concluded because some patients can relapse and require definitive surgical intervention or removal of foreign material.

Pericarditis

Bacterial pericarditis in children is a rare complication of *S. aureus* BSI or other focal (usually pleural) infection. Pericarditis should be suspected in any patient with BSI and cardiomegaly. Signs and symptoms include fever, dyspnea, cough, and precordial chest pain. The chest radiograph shows an enlarged heart, and echocardiography demonstrates the presence of pericardial fluid. The diagnosis is made by examination of the pericardial fluid for inflammatory cells and bacteria. Management includes urgent pericardial decompression, closed or open pericardial drainage, and parenteral antimicrobial therapy.[153–155] Mortality is due to cardiac tamponade or the systemic inflammatory response syndrome; the likelihood of both these complications is decreased by early medical and surgical treatment. Patients who develop constrictive pericarditis require pericardiectomy.

Suppurative Phlebitis and Septic Thrombophlebitis

Suppurative phlebitis and septic thrombophlebitis are serious endovascular infections that occur along a continuum of clinical severity; they are most commonly caused by *S. aureus.* Suppurative phlebitis usually occurs in a catheterized vessel wall and is characterized by a fluctuant, palpable vein that is warm, tender, and erythematous; pus sometimes can be found at the catheter insertion site or by needle aspiration. Infection can progress to obstruction of the vessel or dissemination of infected thrombi to other sites, or both. The treatment of suppurative phlebitis includes removal of a device, drainage or resection of the infected segment of the vessel, and IV antimicrobial therapy.

Septic thrombophlebitis also occurs in association with invasive *S. aureus* infection without catheterization of the infected vessel. The veins involved usually are major deep veins, especially pelvic or lower extremity vessels, and they commonly are contiguous with an area of osteomyelitis, pyogenic arthritis, pyomyositis, or other soft tissue infection.[118] Longterm IV antibiotic therapy is warranted for this serious endovascular infection, with its attendant severe complications and mortality. Anticoagulant therapy and placement of an inferior vena cava filter are considered when infected clots disperse septic emboli to the lungs.[156]

Central Nervous System Infections

Meningitis

S. aureus meningitis can occur as a complication of BSI or endocarditis, or from extension of a parameningeal focus, including sinusitis, osteomyelitis of the skull bone, subdural empyema, epidural abscess, or rupture of a brain abscess into the lateral cerebral ventricles or the subarachnoid space. Congenital anomalies, such as a dermal sinus or meningomyelocele, can provide a portal of entry. Any neurosurgical procedure increases the risk of staphylococcal meningitis; insertion of a cerebrospinal fluid (CSF) shunt is the most common predisposing procedure.[157]

Treatment consists of parenteral antimicrobial therapy for 3 to 6 weeks, depending on the pathophysiology of the meningitis and removal of a device when present. (Treatment of device-related infection is discussed later in the chapter.)

Brain Abscess

A brain abscess caused by *S. aureus* can result from direct extension of an adjacent infectious focus (e.g., sinusitis,[104] mastoiditis, otitis media); from inoculation of bacteria during a surgical procedure or as a consequence of trauma; or from seeding of the brain during bacteremia. A brain abscess more frequently complicates *S. aureus* BSI than BSI due to other pathogens[158,159] (see Chapter 46). An *S. aureus* etiology should be considered, especially when brain abscess complicates severe *S. aureus* BSI or the patient has had a neurosurgical procedure or penetrating trauma. Cyanotic congenital heart disease also is a predisposing risk factor.[160]

Clinical features of brain abscess in children include headache, vomiting, irritability, focal neurologic defect, seizures, or other manifestations of increased intracranial pressure. The onset of symptoms can be insidious, depending on the pathophysiology; fever can be absent or low grade. The physical examination findings depend on the location of the abscess. Signs of meningitis are expected only if the abscess ruptures into a ventricle.

Imaging techniques are most often definitive in diagnosing a brain abscess. Enhanced MRI is superior to CT, although both modalities are useful.[161] The principal advantages of MRI are the abilities to distinguish the central core of an abscess from a surrounding area of ring enhancement, identify adjacent areas of cerebral edema, and detect abscesses in the posterior fossa.

Treatment consists of parenteral antimicrobial therapy and surgical drainage of the abscess, frequently by aspiration. In rare cases enucleation of the abscess is performed. Evolving abscesses in the non-necrotizing cerebritis stage and some small intracerebral abscesses can be treated with antimicrobial agents alone.[158] Corticosteroid therapy is limited to cases in which increased intracranial pressure is an important component. Patients typically are treated with antimicrobial agents parenterally for 6 weeks. Mortality associated with brain abscess is relatively low, but up to 60% of patients have neurologic sequelae, most commonly seizures.[162]

Spinal Epidural Abscess

S. aureus is the most common cause of a spinal epidural abscess, which is a collection of purulent material external to the dura in the spinal canal, usually in the posterior aspect of the thoracic or lumbar vertebrae. Abscesses arise as a result of seeding of the epidural space during BSI or through direct extension of an adjacent focus of infection, such as pyomyositis or osteomyelitis. Complaints in children can be nonspecific and include fever, vomiting, lethargy, and irritability. Localized tenderness and refusal to lie prone also can be noted. In older children, localized or radicular pain can be present. Paresis of limb muscles and loss of bowel or bladder control are specific and ominous signs because paralysis and loss of sensory modalities at levels below the affected area can ensue rapidly. A history of a clinical illness compatible with bacteremia sometimes is elicited.[163]

Spinal epidural abscess must be distinguished from diskitis, extradural neoplasm, hematoma, disk herniation, and vertebral osteomyelitis. MRI is the diagnostic procedure of choice.[164] Lumbar puncture is deferred when this diagnosis is suspected; if it is performed, CSF findings are similar to those in other parameningeal infections (i.e., a variable, modest pleocytosis, normal glucose, and modestly increased protein concentration).

Therapy includes immediate surgical decompression, debridement of the epidural space, and parenteral antimicrobial therapy, which generally is administered for 6 weeks.[165] Medical management alone is rarely considered in immunocompetent patients with a normal or stable neurologic examination and no signs of septicemia. Continuous reassessment is necessary to identify progressive pain or the onset of any neurologic abnormality that necessitates urgent surgery.[166]

Device-Related Infections

Indwelling Vascular Catheters

Staphylococci are the most common causes of catheter-associated infections. For peripheral venous catheters, *S. aureus* is the most common infecting species; for central venous catheters (CVCs), coagulase-negative staphylococci are recovered more commonly. Cutaneous colonization at the insertion site is the most important predictor of catheter-associated infections related to short-term, percutaneously inserted catheters. For surgically implanted CVCs, organisms introduced through the hub and lumen are the most important source of infection.

Local redness, pain, and warmth at the site of a simple peripheral catheter suggest local phlebitis, which is managed by removal of the device. Diagnosing a central line–associated BSI (CLABSI) can be more difficult. Fever and the presence of pain, fluctuance, erythema, purulence or soft tissue infection at the site suggest CLABSI. Most often, however, the catheter entrance site appears normal.

Blood for culture is taken via the catheter; a positive culture can represent CLABSI or BSI from another source. Isolation of *S. aureus* should not be regarded as the result of a procedural contaminant; repeated samplings or, occasionally, blood drawn simultaneously by venipuncture help to clarify the issue. Semiquantitative culture of the catheter tip after removal can implicate the catheter as the infectious nidus when the colony count exceeds 15 colonies; a negative culture of the catheter tip does not exclude CLABSI.

S. aureus exit-site infections, whether in the presence of a tunnel track infection or BSI, are managed by removing the catheter and administering antimicrobial therapy. Because of the propensity of *S. aureus* BSI to persist and to cause clinical sepsis or to seed the endocardium, abdominal viscera, brain, lung, or bone, many experts recommend removal of an intravascular catheter when *S. aureus* infection is documented, even in the absence of an exit-site infection.

Vancomycin is the preferred empiric therapy for suspected *S. aureus* catheter-associated infection. Combination bactericidal therapy and an extended course of antimicrobial therapy (e.g., 4 to 6 weeks) frequently are recommended because of the known tendency of *S. aureus* BSI to seed and form abscesses at multiple sites. This point is controversial because of the lack of specific data (see Chapter 100). Consistent use of a "bundle" of techniques for placing and handling catheters is among the measures that have been shown to reduce the infection rate; these measures include skin disinfection with chlorhexidine, an aseptic placement technique, use of a BioPatch dressing, dedicated teams for ongoing catheter care, and the earliest possible removal of the catheter.

Cerebrospinal Fluid Shunt Devices

A contaminated CSF shunt or subcutaneous reservoir device is the most common predisposing cause of staphylococcal meningitis.[157] Presumably *S. aureus* gains access to the catheter during surgical insertion, although the device and CSF can be seeded by a subsequent adjacent primary SSTI or tract infection or during BSI – the presence of the catheter increases the likelihood that the organism will survive and multiply.

Most CSF shunt infections occur within 2 months of shunt placement or revision. Low-grade fever and dysfunction of the shunt are variably present. For ventriculoperitoneal (VP) shunts, symptoms and signs attributable to peritonitis commonly can be present.[167,168] If the patient had recently undergone surgery, a wound infection may be evident. A first episode of an *S. aureus* shunt infection is predictive of a subsequent *S. aureus* shunt infection.[169]

Examination of the CSF (typically obtained by percutaneous puncture of the shunt reservoir/tubing) may reveal only mild abnormalities, such as modest pleocytosis, a normal glucose level, and a normal or minimally elevated protein concentration. Microorganisms infrequently are visualized on Gram stain. Culture of CSF is the most sensitive test; however, culture of CSF obtained by lumbar puncture frequently is not diagnostic of a VP shunt infection.

Most experts recommend combined medical and surgical treatment for CSF shunt infections. Typically a temporary external ventricular drain is used, while IV antimicrobial therapy is administered, until the CSF is sterile and inflammation subsides, at which time a new shunt can be placed.[170,171] The timing of this procedure is important – insertion of the new catheter into an infected field must be avoided. However, maintaining an externalized catheter as a drainage device carries its own risk of infection, which accelerates after 5 to 7 days of use.

Toxin-Mediated Syndromes

Staphylococcal Food Poisoning

Staphylococcal food poisoning is caused by ingestion of *S. aureus* enterotoxins. It accounts for up to one third of foodborne gastrointestinal illnesses (see Chapter 59). Protein-rich foods (e.g., ham and chicken) often are implicated as the outbreak source, as are dairy products and egg and potato salads. The individual who inadvertently inoculates the food with *S. aureus* may have a clinical infection but usually is colonized asymptomatically.[172,173]

Illness begins shortly after consumption (4 hours on average) because ingestion of preformed toxin causes the clinical manifestation. Classic symptoms are nausea, vomiting, abdominal pain, and diarrhea; headache and prostration are less common. Fever occurs in about 25% of patients. Hospitalization is required infrequently, and death occurs rarely.

S. aureus can be isolated from the vomitus or feces of ill people. Culture of the contaminated food may yield the offending organism. Therapy is supportive; antibiotics are not useful. The syndrome can be prevented by proper handling of food and careful hygiene practices by food handlers. When cases are recognized, the Department of Public Health must be notified.

Staphylococcal Scalded Skin Syndrome

SSSS is an illness mediated by exfoliative toxins ETA and ETB.[90,91] Hematogenous spread of the toxins produces fever and widespread erythema of the skin, which can be tender and quickly forms thin-walled, fluid-containing bullae that rupture, leaving a moist base of skin. Gentle friction applied to the skin produces Nikolsky sign, a sloughing of superficial sheets of skin (see Fig. 13.2). Desquamation follows rapidly and can be widespread, especially in the neonate.[174,175]

SSSS is diagnosed clinically or by isolation of *S. aureus* from a local site (not necessarily the exfoliating site), ideally with demonstration by the isolate of toxin production or the toxin gene. Histologic evaluation of the skin reveals the separation of skin layers at the granular layer within the epidermis, rather than the separation of the dermis and epidermis seen in drug-induced toxic epidermal necrolysis.[176]

Management of SSSS is primarily supportive, and careful attention is paid to electrolyte levels because fluid shifts can occur across the denuded skin. Antiseptic measures should be taken to prevent infection of the unprotected, affected areas. Parenteral antimicrobial therapy is administered to reduce the staphylococcal burden. Topical antimicrobial agents are not helpful.[176]

Toxic Shock Syndrome

TSS is caused by *S. aureus* strains that produce TSST-1 or certain enterotoxins (specifically SEB and SEC).[177] It is characterized by fever, rash, hypotension, and multisystem organ dysfunction[178] (Box 115.1). The incidence of TSS peaked in the early 1980s; the condition was attributed to the use of superabsorbent tampons by menstruating adolescents and women.[179] Subsequent public education and manufacturing regulations helped reduce the number of TSS cases, and now nonmenstrual TSS accounts for approximately one half of all TSS cases.[180]

Box 115.1

Staphylococcal Toxic Shock Syndrome: Clinical Case Definition

An illness with the following clinical manifestations:

Fever: Temperature >38.9°C (102°F)

Rash: Diffuse macular erythroderma

Desquamation: 1–2 weeks after onset of illness, particularly on palms and soles

Hypotension: Systolic blood pressure ≥90 mm Hg for adults or less than 5th percentile by age for children <16 years; orthostatic drop in diastolic blood pressure ≥15 mm Hg from lying to sitting, orthostatic syncope, or orthostatic dizziness

Multisystem involvement: 3 or more of the following:

1. Gastrointestinal: Vomiting or diarrhea at onset of illness
2. Muscular: Severe myalgia or creatine phosphokinase level ≥2 times the upper limit of normal for laboratory

3. Mucous membrane: Vaginal, oropharyngeal, or conjunctival hyperemia

4. Renal: Blood urea nitrogen or creatinine ≥2 times the upper limit of normal for laboratory or urinary sediment with pyuria (≥5 leukocytes per high-power field) in the absence of urinary tract infection

5. Hepatic: Total bilirubin, serum glutamic-oxaloacetic transaminase (SGOT), or serum alanine aminotransferase (ALT) or aspartate aminotransferase (AST) ≥2× the upper limit of normal for laboratory

6. Hematologic: Platelets $<100{,}000/\text{mm}^3$

7. CNS: Disorientation or alteration in consciousness without focal neurologic signs when fever and hypotension are absent

Negative results on the following tests, if obtained:

1. Blood, throat, or cerebrospinal fluid cultures (for all microorganisms except *Staphylococcus aureus*)

2. Rise in antibody titer to *Rickettsia* or *Leptospira* species or rubeola

Modified from Wharton M, Chorba TL, Vogt RL, et al. Case definitions for public health surveillance. MMWR Recomm Rep 1990;39:1–43.

Risk factors for TSS include colonization and disruption of the skin, colonization of mucous membranes, or any infection caused by a toxin-producing strain of *S. aureus.* TSS often is associated with surgery or trauma, manifesting several days after the event. The sudden onset of fever, chills, headache, vomiting, sore throat, myalgia, and diarrhea is followed by hypotension, respiratory distress, edema, and rash within 24 to 48 hours. Dizziness, listlessness, and disorientation are clues to hypotension and cerebral dysfunction; coma can ensue.

The initial *S. aureus* focus can show no signs of inflammation or purulence. Initially the rash can appear like that seen in scarlet fever, but it classically is described as diffuse erythroderma, or "sunburn." The rash typically desquamates 1 to 2 weeks after the onset of illness, most notably on the palms and soles.

Mucous membrane involvement includes conjunctival hyperemia, strawberry tongue, beefy red oropharyngeal membranes (sometimes with ulcerations), and lesions representing reactivation of the herpes simplex virus.

A vaginal culture yields the organism in 85% of menstrual TSS cases. In nonmenstrual TSS cases a nasopharyngeal or a wound culture may yield *S. aureus;* a blood culture should be obtained (to diagnose concurrent BSI) but is seldom positive.

Management consists of treating intravascular volume depletion, shock, and respiratory failure, in addition to the *S. aureus* infection. Any relevant focus of infection should be drained and any foreign body removed if possible. IV antimicrobial therapy, including an antibiotic that inhibits protein synthesis (e.g., clindamycin or linezolid), may be preferable. The response to effective therapy can be rapid. For a patient who does not respond to these interventions, most experts recommend immune globulin intravenous (IGIV), based on the presence of antibody to staphylococcal enterotoxins and TSST-1.[181,182] End-organ failure, particularly renal failure and acute respiratory distress syndrome, can occur within the first few days of illness and are responsible for the attendant 3% mortality rate.

Severe Sepsis Syndrome

Severe sepsis syndrome is defined as isolation of *S. aureus* from a clinically important site, hypotension (i.e., systolic blood pressure less than the 5th percentile for age for children or less than 90 mm Hg for adults), and respiratory distress syndrome or respiratory failure, in addition to involvement of the central nervous system (CNS), liver, kidneys, muscles, or skin; or abnormal hemostasis; or the presence of leukopenia or thrombocytopenia. Severe sepsis syndrome is similar to TSS but does not meet all the clinical criteria for TSS, and the *S. aureus* isolates do not produce TSST-1.[81]

Increasingly, severe sepsis occurs in children and adolescents with no underlying medical conditions or other identifiable risk factors.[81,183–185] Both MSSA and MRSA are implicated; genes encoding PVL frequently are identified in the infecting strain.

A primary infectious process (e.g., pyogenic arthritis or pneumonia) often is identified before clinical deterioration begins. However, patients can have an overwhelming infection and experience subsequent rapid decline without a primary tissue site of infection.[81,183,184] Skin lesions are common and manifest as erythroderma, pustules, petechiae, and/or purpura. Waterhouse-Friderichsen syndrome,[186] staphylococcal purpura fulminans,[187] and necrotizing fasciitis have been reported.[188]

The diagnosis is made by isolation of *S. aureus* from a clinically important site, such as the blood, a joint space, or respiratory secretions (with concomitant systemic illness). A high index of suspicion is critical to instituting appropriate parenteral antimicrobial therapy and aggressive cardiopulmonary support. Mortality rates based on reviews of case reports approach 64%.[183]

Management

Treatment of invasive *S. aureus* infections should be rapid and aggressive. IV antimicrobial therapy should be started promptly, and the source of BSI and sites of possible metastatic infection should be sought aggressively. Abscesses should be drained, and CVCs or other foreign bodies should be removed when possible. Associated endocarditis or other endovascular infections always should be considered in patients with *S. aureus* BSI because this species has a tropism for endothelial cells, and organisms with the PVL gene have the propensity to cause thrombosis and thromboembolism.[118,189,190]

If rapid improvement does not occur or BSI continues after more than 24 hours of therapy, the therapeutic approach should be carefully reevaluated because irreversible organ damage can progress rapidly. Once the antimicrobial susceptibility of the organism is known, therapy should be tailored to use the appropriate antimicrobial agent or agents with the narrowest appropriate spectrum of activity.

The CA-MRSA epidemic has refocused attention on the importance of adjunctive local treatments, such as incision and drainage. For many purulent SSTIs, incision and drainage may suffice. Guidelines have been published for management involving antibiotics and drainage.[98,191] Because susceptibility to β-lactam antibiotics cannot be assumed, obtaining a specimen for culture is essential for patients who require antibiotic treatment, to further guide therapy.[192]

Antistaphylococcal Agents

The compounds presented in the following sections are discussed further in Chapter 292.

β-Lactam Antibiotics

Previously, semisynthetic β-lactam penicillins (nafcillin, oxacillin, cloxacillin, and dicloxacillin), were the gold standard for treatment of staphylococcal infections. These agents inhibit cell wall synthesis and thus are bactericidal, well tolerated, and have a long record of therapeutic effectiveness. When an MSSA strain is isolated, β-lactams are the drugs of choice for serious staphylococcal infections. Parenteral compounds in wide use in the U.S. include oxacillin and nafcillin; dicloxacillin is available for oral use, although some children find the taste of the suspension unpleasant.

The combination drugs made up of a β-lactam plus a β-lactamase inhibitor (i.e., (ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, and piperacillin-tazobactam) are active against MSSA but offer no advantage over the semisynthetic penicillins. The antistaphylococcal activity of the so-called first-generation cephalosporins is superior to that of later generations of cephalosporins. Cefazolin (for parenteral administration) and cephalexin (for oral administration) are useful class compound examples; their efficacy is similar to that of the semisynthetic penicillins for the treatment of MSSA infections that are not life threatening, and cefazolin is associated with fewer episodes of premature drug discontinuation and drug-emergent events.[193]

Until 2010 none of the β-lactam antibiotics, β-lactamase inhibitors, or cephalosporins had proved useful for therapy of MRSA infections. However, in 2010 the drug ceftaroline was licensed for treatment of CAP and complicated SSTIs. Designated a fifth-generation cephalosporin, ceftaroline is active against MRSA strains and has broad-spectrum activity against many gram-positive and gram-negative bacteria. Ceftaroline has been used as salvage therapy in adults with invasive MRSA infections who have responded slowly to vancomycin. No data have been reported on the drug's use in children,[194] although evaluation is underway.

Clindamycin

Clindamycin is a lincosamide antibiotic that inhibits protein synthesis at the chain elongation step by interfering with transpeptidation of the 50S ribosomal subunit. Most HA-MRSA isolates are resistant to clindamycin, but most CA-MRSA isolates are susceptible,[191] particularly in children.[60,77,98,195,196] Despite its increasingly frequent use in the treatment of CA-MRSA infections, clindamycin is not licensed by the U.S. Food and Drug Administration (FDA) for this purpose.

Erythromycin resistance of *S. aureus* is prevalent and can impair the effectiveness of clindamycin. The erythromycin ribosomal methylase *(erm)* gene codes for the enzyme that modifies the binding site not only for macrolides, but also for lincosamides and streptogramin B antibiotics. Consequently, cross-resistance to these three classes of antibiotics, the so-called macrolide–lincosamide–streptogramin B (MLS_B) phenotype, is common among *S. aureus* isolates.[197] Phenotypic expression of the MLS_B phenotype can be constitutive or inducible with exposure to a macrolide. When it is constitutive, the isolate tests as resistant to all MLS_B antibiotics. When it is inducible, however, the isolate tests as resistant to erythromycin and susceptible to clindamycin.

Clinical laboratories test for inducible clindamycin resistance with the disk diffusion D-test or with automated simultaneous broth dilution testing in the presence of erythromycin (see Chapter 290 and Fig. 290.4).[198,198] To date, although the incidence of erythromycin resistance among CA-MRSA isolates is high, the incidence of clindamycin resistance is not. Clinicians should be aware that treatment failure with clindamycin is possible if the target organisms have demonstrable inducible resistance in vitro.[198,199]

Clindamycin also is a potent suppressor of bacterial toxin synthesis. Clindamycin therapy may be clinically superior in toxin-mediated staphylococcal syndromes, although explicit data are lacking. When clindamycin is used in this setting, combination therapy with oxacillin or nafcillin, or with vancomycin, frequently is used.

Clindamycin is bacteriostatic and does not cross the blood-brain barrier; it is not used alone in the treatment of endocarditis or other intravascular or CNS infections that can occur during *S. aureus* invasive infection. The poor taste of clindamycin suspensions can hamper adherence to oral therapy in outpatients.

Clindamycin resistance rates among *S. aureus* isolates, both MRSA and MSSA, should be monitored locally. In areas where the resistance rates exceed 10% to 15%, empiric therapy with this agent probably should be avoided.[200–202]

Vancomycin

Vancomycin is a glycopeptide that inhibits synthesis and assembly of the second stage of cell wall peptidoglycan in gram-positive bacteria. It is the therapeutic agent of choice for HA-MRSA infections. However, the emergence of VISA and VRSA isolates, in addition to the so-called MIC creep to 1 to 2 μg/mL, has the potential to limit the effectiveness of vancomycin.[203–205] Some experts recommend the use of higher doses in serious infections to elicit higher serum trough levels of vancomycin; however, the effectiveness, necessity, and safety of these strategies in children is controversial.[98]

Vancomycin should be considered for children suspected of having serious CA-MRSA infections, such as SSTIs with systemic manifestations that require hospitalization, severe sepsis, TSS, CNS infection, necrotizing pneumonia, and necrotizing fasciitis. Considerations for empiric use for osteoarticular infections include the local prevalence of CA-MRSA, degree of illness, site of infection, and adequacy of culture specimens obtained to guide therapy.

Because vancomycin is less bactericidal than oxacillin or nafcillin for MSSA and can result in treatment failure or relapse, it should not be used for therapy of MSSA infections unless it is necessary (e.g., the patient has a type 1 allergic reaction to β-lactam agents). In severely ill patients, semisynthetic penicillin frequently is given in addition to vancomycin until culture and susceptibility test results are available. Vancomycin is available only in IV form for use in the therapy of *S. aureus* infections, and the concentration obtained in the alveolar space is poor. Oral vancomycin is not absorbed.

Oritavancin

Oritavancin is a semisynthetic lipoglycopeptide that was approved by the FDA in 2014 for the treatment of SSTIs caused by gram-positive organisms. Oritavancin is active against MRSA, VISA, VRSA, daptomycin-nonsusceptible isolates and vancomycin-resistant *Enterococcus*. Due to a long serum half-life (393 hours), concentration-dependent bactericidal activity, and a three-pronged mechanism of action, a single dose of oritivancin has been shown to be noninferior to repeated vancomycin dosing for treatment of SSTI in adults.[206,207] Due to slow tissue elimination, no oritivancin dosing adjustments are needed in patients with renal or hepatic insufficiency.

In addition to achieving steric inhibition of transglycosylation, oritavancin can bind pentaglycyl cross-bridges, which inhibits peptidoglycan transpeptidation and cross-linking. It interacts with the bacterial cell membrane, leading to depolarization, increased membrane permeability, and cell death of both stationary and exponential growth phase bacteria. These mechanisms distinguish oritavancin from vancomycin.[208] Membrane depolarization also provides effectiveness against daptomycin-nonsusceptible bacteria. To date, no oritavancin resistance has been detected in clinical isolates of *S. aureus*. Lack of evaluation in children and expense currently limit its use.

Dalbavancin

Dalbavancin is a semisynthetic lipoglycopeptide derivative of teicoplanin. It contains a long lipophilic side chain that extends its potency and half-life. Dalbavancin has been approved by the FDA for the treatment of SSTI caused by gram-positive organisms, and it is dosed once per week. Dalbavancin binds to the D-ala-D-ala residue, destabilizing the cell membrane and resulting in bacterial cell death. Active against both MSSA and MRSA, dalbavancin is more potent than vancomycin against strains with a vancomycin MIC of 2 μg/mL or less. The kinetics in children 12 to 17 years of age appear to be similar to those in adults[209]; no data are available for younger children. Dalbavancin is noninferior to vancomycin and linezolid. Because of its extended half-life, one or two doses of dalbavancin can be used after incision and drainage to treat SSTIs in ambulatory patients. The drug is very expensive and must be given parenterally.

Linezolid and Tedizolid

Linezolid and tedizolid are oxazolidinones that inhibit protein synthesis by binding to the 50S ribosomal subunit during the formation of the initiation complex.[210] They have broad in vitro activity against MRSA, GISA, VISA, and VRSA isolates. They are well tolerated, and linezolid is as effective as vancomycin in children with SSTIs and pneumonia caused by MRSA.[211–213] The oral bioavailability of both compounds is almost 100%, which facilitates transition from IV to oral therapy.

Linezolid and tedizolid are bacteriostatic against *S. aureus* and therefore are not preferred for the treatment of endocarditis or other intravascular infections. If possible, linezolid should be avoided in patients taking adrenergic or serotonergic agents.[214] Drug interactions may occur less frequently with tedizolid than with linezolid. Both compounds can be associated (possibly to a lesser degree for tedizolid) with the development of thrombocytopenia, which can be idiosyncratic and severe; anemia; and neutropenia.[215] The complete blood count should be monitored in patients receiving therapy for longer than 2 weeks, those with underlying myelosuppression, or those taking other drugs that cause bone marrow suppression. A small number of cases of optic and peripheral neuropathy and lactic acidosis have been reported in adults during prolonged courses of therapy with linezolid.

Resistance to linezolid has emerged in patients receiving longterm therapy. Resistant isolates have mutations in the 23S rRNA gene in the domain V region, of which *S. aureus* has five copies.[216,217] A mutation in two or more of the rRNA genes is required for the resistant phenotype. This kind of resistance probably also occurs with tedizolid. Additional resistance mechanisms have been identified in ribosomal proteins L4 and L3. Plasmid-borne *cfr* genes have been identified that encode a methyltransferase that mediates linezolid resistance by methylation of carbon-8 on the 23S rRNA base. *cfr* genes confer cross-resistance to phenicols, lincosamides, pleuromutilins, and streptogramin A antibiotics.[218] Available data suggest that isolates with *cfr* genes are nonetheless responsive to tedizolid therapy.[219]

Both linezolid and tedizolid are available in IV and oral forms. Linezolid is available in a convenient pediatric suspension. The compounds are extremely expensive, and negotiation with some third-party payers may be required for each use. Patients also can experience delays in procuring linezolid from private pharmacies that do not stock it routinely. A generic form of linezolid was recently released that costs about 20% less.

Trimethoprim-Sulfamethoxazole

TMP-SMX interferes with the biosynthesis of tetrahydrofolic acid, which is essential for microbial synthesis of proteins and nucleotides. Although most *S. aureus* isolates are susceptible in vitro, TMP-SMX was seldom used to treat *S. aureus* infections until the recent epidemic of CA-MRSA. Reports now are available on clinical experience using TMP-SMX to treat CA-MRSA SSTIs[220] or more severe *S. aureus* infections. One study suggested that the efficacy of TMP-SMX was similar to that of clindamycin for skin infections of unspecified cause, including cellulitis.[220] For the treatment of invasive *S. aureus* infection, data show IV TMP-SMX to be inferior to vancomycin for MSSA and only equivalent to vancomycin for MRSA (these data were obtained before the CA-MRSA era[221]). The observation that thymidine can be released from injured tissue or bacteria has suggested a possible explanation for discordant in vitro and clinical outcomes.[222] Additional information is needed to establish the appropriate role for TMP-SMX in the anti–*S. aureus* armamentarium.

Tetracyclines (Including Tigecycline)

Tetracyclines inhibit bacterial protein synthesis by binding to the

30S ribosomal subunit, thereby blocking the attachment of the transfer RNA amino acid to the ribosome. Tetracyclines such as doxycycline and minocycline have emerged as alternative oral antimicrobial agents for mildly to moderately ill patients with MRSA SSTIs. Most isolates are susceptible in vitro.[191,223]

Tigecycline, a novel glycylcycline that was recently licensed for parenteral use, has potent activity against *S. aureus* in vitro, regardless of methicillin or vancomycin susceptibility.[224,225] However, in 2010 the FDA issued a warning linking tigecycline to an increased mortality risk in patients being treated for hospital-acquired pneumonia, CAP, complicated intra-abdominal infections, and complicated SSTIs; this suggests that tigecycline should not be used in the treatment of *S. aureus* infections.

All tetracyclines are bacteriostatic and should not be used for the treatment of endocarditis or other intravascular or CNS infections. Tetracyclines also should not be used to treat pregnant women.

Quinupristin-Dalfopristin

The drug Synercid is a combination of two streptogramin antibiotics, one from group B (quinupristin) and one from group A (dalfopristin), in a 30/70 ratio. Quinupristin-dalfopristin has good in vitro activity against *S. aureus,* including MRSA. The two streptogramins bind to sequential sites on the 50S ribosomal subunit and have a synergistic bactericidal effect that results from inhibition of protein synthesis.[226] Recent trials have shown a lower bacteriologic success rate compared with standard therapy.[227] Quinupristin-dalfopristin is not cross-resistant to *S. aureus* isolates with MLS_B resistance because the streptogramin A component remains active; however, few data are available to ensure the clinical validity of this issue. Quinupristin-dalfopristin is available only in IV form, and evaluation in children has been minimal. Infusion site inflammation, thrombophlebitis, arthralgias, drug-drug interactions, myalgias, gastrointestinal toxic effects, and increased serum unconjugated bilirubin concentrations have limited widespread use.

Daptomycin

Daptomycin is a novel cyclic lipopeptide with a mechanism of action that is not completely understood. It appears to bind to the gram-positive bacterial cell membrane, which is followed by calcium-dependent insertion[228] that results in a decrease in membrane potential, causing cell death by rapidly stopping DNA, RNA, and protein synthesis. It has potent bactericidal activity against MRSA.[229] Daptomycin was comparable to vancomycin in the treatment of complicated SSTIs[230]; however, it showed decreased effectiveness for the treatment of CAP compared with standard treatment, probably because of its propensity for binding surfactant.[231] Daptomycin has been licensed by the FDA for the treatment of complicated SSTIs, BSI, and right-sided endocarditis; however, it is not approved for the treatment of left-sided endocarditis.[232] Daptomycin is available in IV form only. Studies evaluating its use in children suggest good efficacy.[233] When the cell wall is thickened (e.g., in a VISA isolate or after exposure of an *S. aureus* isolate to vancomycin), resistance to daptomycin becomes evident, presumably because the compound cannot reach its cell membrane target.[234,235] Resistance to daptomycin can occur during therapy and was documented in 6 of 120 patients receiving daptomycin for endocarditis, or BSI.[236] In addition, daptomycin-resistant isolates can be cross-resistant to vancomycin.[235]

Telavancin

Telavancin is a lipoglycopeptide that was licensed by the FDA in 2009 for the treatment of complicated SSTIs. The compound depolarizes bacterial membranes and inhibits cell wall formation. No formal evaluation has been done in children. The drug is administered once daily. Telavancin carries a “black box” warning that it worsens renal dysfunction. As can vancomycin, telavancin can cause red man syndrome. A few resistant isolates have been, obtained although the mechanism is not known.

Rifampin

Rifampin is a bactericidal agent that blocks protein synthesis by inhibiting RNA polymerase. It is highly active against almost all *S. aureus* isolates, but resistance emerges rapidly when rifampin is used as monotherapy. Combination regimens using rifampin with clindamycin, TMP-SMX, or doxycycline sometimes are recommended for the treatment of CA-MRSA infections or for treating device- or prosthesis-associated *S. aureus* infections. Whether such regimens are more effective is unclear. Rifampin is available in both oral and IV forms, although a suspension suitable for use in young children is not available.

Aminoglycosides

Aminoglycosides (e.g., gentamicin) are potent bactericidal inhibitors of protein synthesis. Aminoglycosides alone are believed to be poorly efficacious against *S. aureus* infections, although they are synergistic with β-lactam antibiotics and vancomycin in vitro. They are commonly used in combination therapy for severe infections, such as endocarditis, but whether this offers a clinical advantage is the subject of controversy.

Empiric Therapy for Community-Associated Infections

CA-MSSA and CA-MRSA skin infections cannot be differentiated on clinical grounds.[192] In areas where CA-MRSA is prevalent, empiric β-lactam therapy is not appropriate. Fig. 115.9 suggests an approach to the management of these cases. Therapy should be adjusted according to in vitro test results. A study sponsored by the National Institutes of Health is underway to determine the optimal oral therapy of *S. aureus* large-lesion SSTI in outpatients.[220] A similar study comparing clindamycin, TMP-SMX and placebo therapies for small abscess will be published (Daum R, et al. In press).

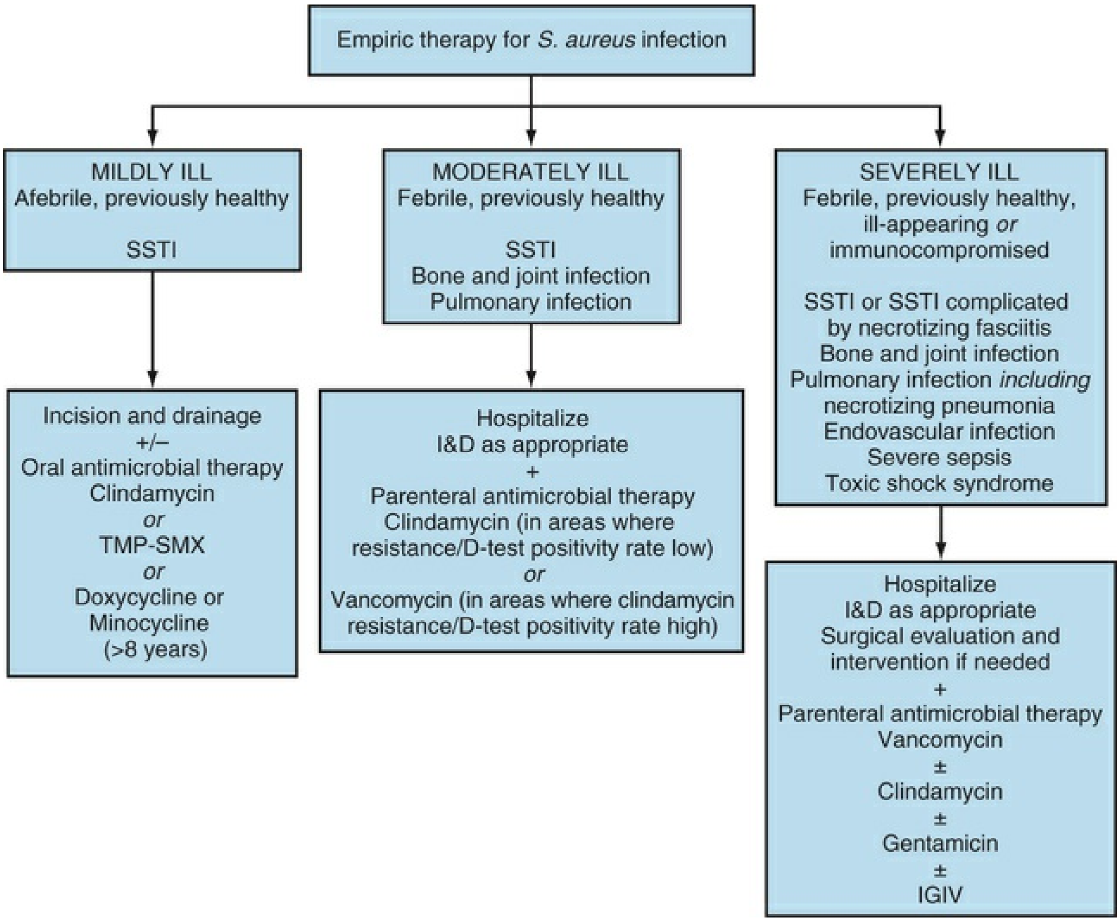

FIGURE 115.9 Schema for the empiric treatment of community-associated *S. aureus* infections, determined by the severity of the illness. SSTI, Skin and soft tissue infection; I&D, incision and drainage; TMP-SMX, trimethoprim-sulfamethoxazole; IGIV, immune globulin for intravenous use.

Empiric Therapy for MRSA Infections Requiring Hospitalization

Vancomycin is indicated for empiric therapy of putative *S. aureus* infections when the patient is severely ill.[98,237] VISA isolates have been identified that are associated with vancomycin treatment failure.[238,239] The Clinical and Laboratory Standards Institute defines VISA as an MIC of vancomycin greater than 2 μg/mL. In 2002 the CDC reported the first documented infection caused by *S. aureus* with high-level resistance (MIC >16 μg/mL) to vancomycin, or VRSA; 12 additional VRSA strains have been isolated since.[87–89,240,241] VISA and VRSA isolates probably occur more frequently than is documented because optimal tests to detect decreased vancomycin susceptibility often are not performed in clinical laboratories.[242]

Information about parenteral therapy with clindamycin, daptomycin, tigecycline, linezolid, telavancin, and other agents useful in the therapy of MRSA infections in hospitalized children can be found in Chapter 292 and in the guidelines established by the Infectious Diseases Society of America.[98,243]

Prevention

Efforts to prevent *S. aureus* HAIs have included general measures such as improved hand hygiene and attention to careful implementation of measures aimed at diminishing infections associated with intravascular catheters. Other efforts aimed specifically at reducing infections caused by MRSA have included identification of MRSA carriers upon hospitalization, and isolation and cohorting of patients who are colonized. Contact Precautions are used in the care of patients with a MRSA infection. Some states have legislated mandatory screening for MRSA upon admission to the hospital or, in some cases, to an intensive care unit. However, such a screening approach has several problems: high cost, focusing finite resources on a single pathogen, lack of agreement on best practices to determine MRSA carriage, lack of evidence-based management when colonization is found, and the insignificant impact of an effective institution-based strategy on MRSA infections in the community.[243]

In the community setting, some sports teams have increased efforts to schedule equipment washing, discourage towel sharing, restrict infected members from play until lesions have healed, and encourage good hygiene among team members.[244,245] Several correctional facilities have introduced practices to reduce the spread of CA-MRSA, as recommended by the Federal Bureau of Prisons.[72] Chlorhexidine-impregnated cloths were used successfully in prisons to reduce the density of skin colonization,[246] and they are frequently are used preoperatively; however, this approach was unsuccessful in preventing SSTIs among military recruits.[247]

MRSA decolonization has been attempted in outbreak situations and to prevent recurrent SSTI, with little success. Few randomized, controlled trials have evaluated the efficacy of topical antibiotics and skin antisepsis in the eradication of *S. aureus* carriage.[99,248–251]

Intranasal mupirocin ointment appears to have the most success in reducing previous HA-MRSA nasal colonization, and it has shown a subsequent decrease in carriage at other body sites. A 5-day application of intranasal mupirocin resulted in decreased short-term rates of colonization, but recolonization occurred in at least one half of the treated subjects, usually within a few months.[99] Unacceptably high recolonization rates, concern about mupirocin resistance,[252,253] and limited data about the drug's effectiveness against CA-MRSA prevent intranasal mupirocin from being recommended for routine use. Focusing on reducing the density of colonization and environmental contamination, as well as improving underlying skin conditions, may be more prudent.

Vaccine Development

A vaccine to prevent *S. aureus* infection remains a formidable challenge. Experts disagree on whether *S. aureus* infections can be prevented by vaccination and, if so, whether such a vaccine should be deployed universally or targeted to high-risk groups.

The traditional idea that production of an opsonophagocytic antibody (or antibodies) correlates with protection has been challenged by available data. In two vaccine trials of types 5 and 8 polysaccharide conjugate vaccine, immunization failed to provide protection against BSI.[254] Recently a protein vaccine containing an iron-scavenging, cell wall–anchored protein (ISDB) was developed. Enrollees in the study of this vaccine were adults undergoing elective cardiac surgery that required a sternotomy. The clinical end point was the occurrence of *S. aureus* mediastinitis or bacteremia. However, the study was halted for lack of efficacy and because of concern that vaccine recipients who developed *S. aureus* invasive infection had a worse outcome than placebo recipients.[16] A clinical trial of a 4-component vaccine, including the capsular antigens manufactured by Pfizer, currently is enrolling adults undergoing elective spinal surgery.

In an initial trial, attempts to protect neonates passively with a high-titer, anti–clumping factor A polyclonal antibody product (Veronate) appeared to have promising results; however, a confirmatory trial did not confirm efficacy (Hetherington S. Personal communication, 2006.). A clinical trial using a monoclonal antibody (pagibaximab) directed against lipoteichoic acid was conducted among small premature infants in an attempt to prevent infections caused by *S. aureus* and coagulase-negative staphylococci; however, efficacy was lacking.

Recent attention has focused on the role of the Th17/IL-17 lymphocyte pathway.[255] One candidate vaccine (rAls3p-N) derived from a *Candida* adhesin protected mice against bacteremic challenge. Efficacy was retained in mice that were B-lymphocyte deficient but not in those that were T-lymphocyte deficient. Adoptive transfer of $CD4^+$ lymphocytes, but not $B220^+$ lymphocytes, transferred immunity. The vaccine apparently stimulates proinflammatory Th1, Th17, and Th1/Th17 lymphocytes, and these cytokines enhance neutrophil recruitment and activation. As of February, 2015, the manufacturer had yet to decide whether to evaluate this vaccine against *S. aureus* in an efficacy trial.

Staphylococcus epidermidis and Other Coagulase-Negative Staphylococci

Philip Toltzis

Staphylococcus epidermidis and other coagulase-negative staphylococci (CoNS), once considered nonpathogenic commensal organisms, now are recognized clearly as potential true pathogens, particularly in hospitalized patients and those with indwelling foreign bodies. Multiple surveys have shown that CoNS are the most frequent cause of nosocomial bloodstream infections (BSIs) around the globe.[1–6] These organisms are implicated particularly in bacteremic disease in patients in the intensive care unit (ICU)[4,5,7–10] and in patients immunocompromised by cancer[11–18] or solid-organ transplantation.[19,20] CoNS account for 20% to 50% of all nosocomial BSIs in these patient groups.

Description of the Pathogen

Staphylococci are members of the family Staphylococcaceae. They are nonmotile, nonspore-forming, catalase-positive bacteria.[21] These organisms are gram-positive cocci that grow in irregular clusters. Staphylococci are among the hardiest of nonspore-forming bacteria and can survive many nonphysiologic environmental conditions. Colonies are round, smooth, raised, and glistening and can be surrounded by a zone of hemolysis when grown on blood-containing media.

In the clinical microbiology laboratory, CoNS are distinguished from *Staphylococcus aureus* by their failure to produce coagulase, an enzyme that coagulates rabbit plasma. Originally, all CoNS were grouped together under the designation *Staphylococcus albus;* by 2015, however, 50 species and numerous subspecies of CoNS had been recognized, based on biochemical and genetic differences (for the current classifications, see the website http://www.bacterio.cict.fr/). Fifteen species are normal human flora: *S. epidermidis, S. haemolyticus, S. hominis, S. saccharolyticus, S. capitis, S. warneri, S. caprae, S. pasteuri, S. saprophyticus, S. cohnii, S. xylosus, S. simulans, S. auricularis, S. lugdunensis,* and *S. schleiferi*.[21] All CoNS primarily are skin commensals, but they can colonize the upper respiratory tract, gastrointestinal tract, genitourinary tract, and mammary glands. Some species exhibit preferential niches for certain areas of the skin, such as *S. capitis* for the sebaceous gland-rich scalp, *S. auricularis* for the external auditory canal, *S. hominis* and *S. haemolyticus* for the apocrine gland–rich axillae and pubis, and *S. saprophyticus* for the female genitourinary tract.

Many clinical microbiology laboratories continue to characterize isolates simply as CoNS. However, commercially available kits can rapidly distinguish CoNS species with an accuracy of 70% to greater than 90%.[21] Most kits include a series of biochemical reactions, although systems based on polymerase chain reaction amplification of ribosomal ribonucleic acid *(rRNA)* and other conserved genes also have been described.[21] Species identification of *S. lugdunensis* and *S. schleiferi* is particularly important because these species cause aggressive disease more typical of *S. aureus*.[22,23] In the laboratory they can be distinguished from most other CoNS because they produce a positive result on a rapid coagulase slide test (reflecting the presence of “clumping factor” rather than bound coagulase); as do other CoNS, however, they test negative with the more definitive coagulase tube assay.[21] Both *S. lugdunensis* and *S. schleiferi* are relatively uncommon on normal human skin, but they can colonize implanted materials, such as catheters and drains. *S. lugdunensis* has been implicated in natural and prosthetic valve endocarditis, septicemia, brain abscess, peritonitis, soft tissue infection, vascular graft infection, prosthetic joint infection, and catheter-related infection.[22–27] *S. schleiferi* rarely has been reported as a pathogen in the United States, but in some European countries it has caused brain empyema, wound infection, osteomyelitis, and BSI.[23,28,29]

Pathogenesis

Colonization is a prerequisite for CoNS disease. CoNS can be isolated from multiple skin surfaces, which suggests that most infections originate from organisms on the skin.[30,31] Most patients who develop a CoNS infection have an obvious disruption of the skin barrier, caused by surgery, placement of a catheter, or insertion of a prosthesis. Systemic infection also can originate from colonized mucous membranes of the pharynx and gastrointestinal tract when organisms enter the bloodstream, either through breaks in the mucosa or by translocation through mesenteric lymph nodes.[32,33]

Unlike *S. aureus,* CoNS typically do not elaborate virulent exotoxins. Consequently, infections caused by most CoNS characteristically are indolent and prolonged, even in compromised patients. The prominence of CoNS as nosocomial pathogens stems largely from their propensity to adhere to the inanimate surfaces of catheters and prostheses and also in their ability, once established, to evade host defense mechanisms and antibiotic activity. Both characteristics are mediated by the production of biofilm, a thick accumulation of bacteria arranged in multilayered clusters that are covered by an extracellular matrix. The importance of biofilm in CoNS pathogenesis has been confirmed repeatedly by demonstrations that mutants deficient in biofilm-related molecules are less likely to cause disease than their isogenic counterparts.[34,35]

The formation of biofilm occurs in three overlapping stages: attachment of the CoNS to polymer surfaces; maturation of the organisms within the biofilm to form a complex, multilayered structure; and detachment, which allows the organisms within the biofilm to disseminate to distant sites.[36–38] (Fig. 116.1). In the first stage, nonspecific factors, including long-range electromagnetic forces and surface hydrophobicity, promote attachment.[39,40] Several bacteria-specific products mediate this seminal stage of attachment. Chief among these is the surface-associated autolysin AtlE, which shows significant homology to the major autolysin of *S. aureus*.[41] AtlE mediates binding to unmodified plastic surfaces indirectly, by altering the hydrophobicity of the bacterial cell wall.[36,37] Two related staphylococcal surface proteins, SSP-1 and SSP-2, are fimbria-like polymers encoded by *S. epidermidis* that further mediate adherence to polymers.[42,43] Once inserted into the body, plastic surfaces become coated with plasma and extracellular host proteins such as fibronectin, fibrinogen, vitronectin, thrombospondin, and von Willebrand factor, and bacterial molecules also bind these host molecules (Fig. 116.1). Several such molecules have been characterized; they are known collectively as microbial surface components recognizing adhesive matrix molecules (MSCRAMMs).[36–38,44,45]

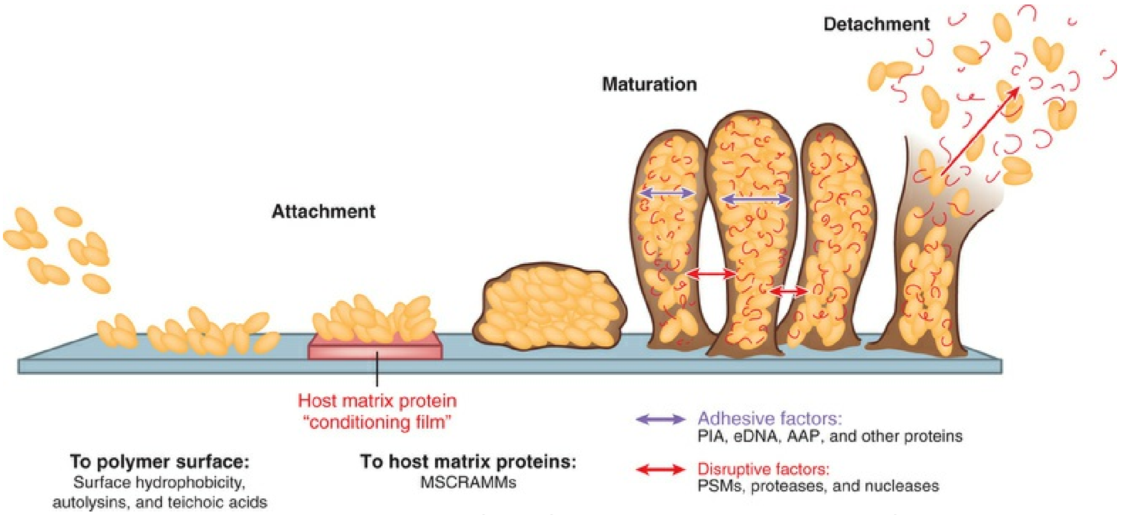

FIGURE 116.1 Phases of biofilm development. Biofilm development includes initial attachment, maturation, and detachment. Attachment can occur directly to a surface (e.g., a polymeric surface of an indwelling medical device) or to a "conditioning film" formed by host matrix molecules. Then biofilm maturation proceeds via the agglomeration of cells, which is dependent on adhesive molecules. Formation of the characteristic channel-containing biofilm structure depends on disruptive forces, which also ultimately

facilitates the last phase of biofilm development, detachment. Molecular determinants that have been shown or are suspected to be involved in the biofilm development phases in staphylococci are noted at the bottom of the illustration. AAP, accumulation-associated protein; eDNA, extracellular DNA; MSCRAMMs, microbial surface *components recognizing adhesive matrix molecules*; PIA, *polysaccharide intercellular adhesin*; PSMs, phenol-soluble modulins. (From Otto M. Staphylococcal infections: mechanisms of biofilm maturation and detachment as critical determinants of pathogenicity. Annu Rev Med 2013;64:175–188.)

After attachment and during the maturation phase, organisms accumulate and form multilayered aggregates; this is the critical stage of biofilm formation (see Fig. 116.1). In 1994, Mack and coworkers found that a *S. epidermidis* transposon mutant that lacked a polysaccharide antigen, called polysaccharide intercellular adhesin (PIA), was unable to form multilayered cell clusters.[46] PIA since has been confirmed as the central molecule in CoNS biofilm production. PIA is encoded by the *icaADBC* gene cluster, which is responsible for its synthesis and modification; mutation of any of the four open reading frames in the *ica* gene locus interferes with maturation of the CoNS biofilm.[36,37,44] The control of *ica* expression is incompletely understood but is influenced by several negative and positive regulators, which presumably promote the production of biofilm under specific environmental conditions.[44,47,48] However, *ica*-negative CoNS that produce biofilm have been identified, indicating the existence of PIA-independent mechanisms of biofilm formation.[49–51] Three candidates are a 140-kd extracellular protein called accumulation-associated protein[52,53]; extracellular matrix binding protein; and extracellular deoxyribonucleic acid (eDNA) released from lysed bacteria; all three of these also may participate in the first (attachment) phase of biofilm formation.[36] These additional molecules add redundancy to the synthetic mechanisms of CoNS, mediating accumulation in organisms with a compromised ability to express PIA.[37]

After attachment and maturation, most biofilm isolates elaborate copious amounts of a complex extracellular material generally referred to as slime.[54] In a hospital-wide survey Ishak and associates[55] found slime production in 13 of 14 clinically significant bloodstream isolates of *S. epidermidis*, but in only 3 of 13 blood culture contaminants and 4 of 27 skin isolates. Studies of infants with CoNS infection have yielded similar results. In independent studies, slime production was noted in 82% of isolates from infants with invasive disease.[56]

The third phase of biofilm formation, detachment, likely is mediated by the formation of channels within the structure that allow the resident bacteria access to nutrients.[37] Quorum-sensing mechanisms in CoNS recognize the bacterial density in the biofilm and convert the replicating populations to a more stationary phase.[37] Additionally, these mechanisms activate the expression of a family of surfactants called phenol-soluble modulins (PSMs), which affect the volume of biofilm and the formation of channels. Under flow conditions such biofilms detach, allowing dissemination of organisms to distant sites.[37] CoNS with disrupted PSM function form biofilms that are more compact and tightly adherent to the plastic surface than the biofilms produced by CoNS with functional PSMs; however, the ability of the former to spread is diminished.

Several biofilm-related molecules are implicated in immune evasion.[57] PIA may render the organism more resistant to neutrophil clearance; *S. epidermidis* organisms that contain *ica* gene mutations and deficient PIA are phagocytosed more readily in vitro and are more susceptible to the toxic effects of neutrophil granules than their isogenic correlates.[35,58] These antiphagocytic properties may make the organism particularly pathogenic in premature infants, who have depressed neutrophil function compared with that of term infants and adults.[59] Slime further functions as a nonspecific physical barrier to cellular and humoral defense mechanisms. In addition, it inhibits neutrophil chemotaxis and phagocytosis and suppresses lymphocyte blastogenesis.[60] Crude extracts of slime can inhibit the antimicrobial action of the glycopeptide antibiotics vancomycin and teicoplanin.[61] This effect appears to be limited to the glycopeptide class of antibiotics because slime extracts produce no change in the minimal inhibitory concentration (MIC) of cefazolin, clindamycin, or rifampin.

CoNS also elaborate a variety of exoproteins. Examples include urease, lipase/esterase, fibrinolysin, DNase, and a number of proteases. For the most part the specific function of these bacterial products remains undetermined. In addition, some isolates produce δ-like toxin, an extracellular hemolysin that resembles the enteropathic δ-toxin of *S. aureus* in size, biologic properties, and antigenicity.[38] This δ-like toxin has cytotoxic effects on intestinal epithelium, and investigators have correlated free toxin in the stool of premature infants with the development of necrotizing enterocolitis (NEC).[62] *S. epidermidis* further produces a number of lantibiotics, or antibiotic peptides containing the unusual amino acids lanthionine or methyllanthionine that can suppress the growth of competing bacteria on skin and mucous membrane surfaces.[38]

S. saprophyticus elaborates a number of factors that may contribute to its ability to cause urinary tract infections (UTIs). A hemagglutinin/adhesin expressed on the surface of *S. saprophyticus* and the surface fibrillar protein SSP both bind to uroepithelial cells, which may explain the peculiar tropism of this species for the urinary tract. *S. saprophyticus* further elaborates a urease, which damages bladder tissue once infection has been established.[63]

Epidemiology

CoNS are acquired early in life; virtually all infants carry them at multiple sites by 2 to 4 days of age.[64] Colonization among healthy people remains ubiquitous beyond the newborn period. Many CoNS responsible for community-associated infections previously were methicillin susceptible, but community strains increasingly have become resistant.[65,66] In one Japanese study, nearly one third of healthy children had nasal colonization with methicillin-resistant CoNS.[66] Although community CoNS have a diverse lineage, a substantial proportion carry the same staphylococcal cassette chromosome mec cassette (SCC*mec*) IV, which is responsible for methicillin resistance in community-associated methicillin-resistant *S. aureus*.[65,66]

Accumulating evidence suggests that, in contrast to the diversity of community-derived CoNS strains, one or more CoNS strains in an individual hospital unit can become predominant over a protracted period. Genetically identical or strongly related organisms have been isolated from a number of patients in an ICU,[67–72] a hematology-oncology unit,[73] a dialysis unit,[74] and even among several wards in a particular hospital.[75,76] Dominant strains can circulate in affected units for many years.[70] The hands of nurses become colonized by hospital-associated CoNS strains soon after employment,[77,78] which highlights the importance of personnel in patient-to-patient transmission. The biologic properties that confer strain predominance are not known, but interference with the growth of surrounding organisms and superior adherence to colonizing surfaces have been speculated to provide a relative survival advantage.

Clinical Manifestations

Bloodstream Infection and Intravascular Catheter–Associated Infection Outside the Newborn Period

CoNS account for roughly one third of all BSIs in children undergoing therapy for leukemia, lymphoma, or solid tumors.[79] In addition, CoNS are an important cause of septicemia in recipients of stem cell transplants.[80] The strongest risk factor for CoNS BSI in these patients is the presence of a central venous catheter (CVC), although immunosuppressive therapy, neutropenia, and chemotherapy-induced gastrointestinal mucositis also are associated risk factors. Mortality from CoNS BSI in this group is reported to be as high as 11%.[79,81] Additionally, *S. epidermidis* is the most common species associated with CVC-associated infections in patients in ICUs with temporary, percutaneously inserted catheters.[82] Infection related to a CVC can occur at the exit site, along the catheter tunnel, or on the intravascular portion. Heavy skin colonization followed by tracking of the organisms along the external surface of the catheter is the principal mechanism of CoNS catheter-associated BSI (also referred to as *central line associated BSI* [CLABSI]).[30,83] Additionally, the catheter hub can become contaminated and organisms can reach the intravascular portion along the inner surface.[30]

In addition to being a frequent cause of CLABSI, CoNS are the most common contaminants of blood cultures, and distinguishing true infection from contamination often is difficult. Some patients who show a positive result on a blood culture for CoNS experience systemic manifestations of infection, such as fever, tachycardia, tachypnea, and hypotension[84]; this makes the diagnosis of true infection relatively secure. In the patient with more subtle signs and symptoms, the most important evidence of true infection is repeated positive results on blood cultures drawn at separate samplings over 1 to 2 days.[85–88] In 2008 the Centers for Disease Control and Prevention established the diagnostic criteria currently used for catheter-associated BSI caused by CoNS (and other skin commensals). These criteria include at least two blood cultures showing a positive result (www.cdc.gov/nhsn/PDFs/pscManual/4PSC/_CLABSIcurrent.pdf).

Several investigators have attempted to define additional diagnostic methods to confirm that the catheter is the source of bacteremia. Quantitative blood cultures are most useful in this regard; specifically, the catheter is likely the source of the infection if the density of organisms in blood obtained through the catheter is at least 5- to 10-fold greater than that in blood drawn simultaneously from a peripheral vessel.[89] When quantitative cultures are unavailable, the relative concentrations of bacteria in central and peripheral blood can be estimated by comparing the time-to-positivity of blood samples taken from the central line and from a peripheral site; a difference in time-to-positivity greater than 120 to 180 minutes suggests that the catheter is the source of infection. However, this comparison is valid only if the samples are of equal volume.[90,91]

Culturing the intravascular portion of the catheter itself is the most reliable method of establishing the catheter as the source. Maki and associates[92] determined that CLA BSI can be confirmed by removing the catheter, rolling the distal 5 to 7 cm of the catheter over an agar surface, and finding growth of 15 or more colonies. The drawback to this method is that it requires removal of the catheter. Fortunately most patients with CoNS exit site infection and roughly 75% of those with BSI arising from a surgically implanted, tunneled catheter can be cured without removing the catheter.[89] Although the risks of recurrent CoNS BSI are increased if the BSI is treated with the line in situ,[93,94] in one study this practice did not contribute to increased mortality.[93] Treatment typically is continued for 10 to 14 days after sterilization of the blood. Catheter removal is almost always necessary when tunnel infection is present. In percutaneous catheters that are not placed surgically, particularly those commonly inserted into patients in the ICU, catheter-related BSI generally requires catheter removal.

Neonatal Septicemia

In the neonatal intensive care unit (NICU), CoNS are recognized worldwide as the most frequent cause of late onset sepsis (sepsis that occurs 7 days or more after hospitalization) in very low birth weight infants.[7,95–99] CoNS also have been implicated as principal pathogens in early onset neonatal sepsis.[8,100–102] In fact, as intrapartum antibiotic prophylaxis to prevent early onset neonatal group B streptococcal infection has become standard, CoNS are second only to gram-negative bacteria as a cause of early onset sepsis.[102,103] Unlike older patients, neonates (especially very low birth weight infants) with CoNS BSI often have focal complications, which frequently are heralded by persistent bacteremia.[104–106] Sites of localized disease include the skin, the heart, an intravenous thrombus, the central nervous system, the lungs, and bones and joints.[96] As in older children, CoNS BSI in the newborn often is a consequence of CVC contamination. CVCs have been implicated in greater than 50% of cases of neonatal CoNS BSI, especially catheters used to infuse parenteral nutrition, particularly lipid emulsions,[107] because intralipid may provide an enriched medium for proliferation of CoNS. Alternatively, the skin, upper airway, and gastrointestinal tract of the critically ill neonate frequently become colonized by CoNS, particularly with prolonged hospitalization, and these sites also may serve as a nidus for bloodborne infection.[95,108–111]

In a critically ill neonate, performing more than a single blood culture before starting antibiotic therapy often is impossible. When CoNS are isolated from a single blood culture, assessment of the likelihood of true infection may be difficult.[112] Infants with septicemia are significantly more likely to have a central catheter or an abnormal hematologic value (white blood cell count $>20{,}000/\text{mm}^3$ or $<5000/\text{mm}^3$, an immature to total neutrophil ratio >0.12, or a platelet count $<150{,}000/\text{mm}^3$). Culture contamination is more likely when infants lack these clinical features.[113,114]

Necrotizing Enterocolitis and Neonatal Focal Intestinal Perforation

Severe, even fatal cases of NEC have been associated with *S. epidermidis* infection.[115] CoNS are a component of the perturbed gut microbiome typical of the critically ill neonate,[116] and this abnormally developing colonic microflora is a key factor potentiating NEC.[117] In one study examining infants who simultaneously experienced NEC and bacteremia, CoNS were the most commonly isolated gram-positive species.[118] Gruskay and associates[119] described a series of neonates who, in contrast to typical NEC, had *S. epidermidis* BSI and associated acute enterocolitis. By definition, all 19 infants had bloody stools with mucus, in addition to signs and symptoms of enterocolitis and an abnormal abdominal radiographic finding. The clinical courses in this series were mild; only one infant had pneumatosis intestinalis, and none required surgical intervention or died. These findings are consistent with CoNS peritonitis caused by focal intestinal perforation, a condition that, in contrast to typical NEC, involves only a limited area of bowel.[120]

Endocarditis

CoNS are an important cause of infective endocarditis. In older children and adults CoNS account for approximately 5% of cases of endocarditis involving previously normal valves.[121,122] Endocarditis in this situation develops after a period of transient BSI with seeding of the valve. CoNS also have been implicated in native valve endocarditis in children with congenital heart disease; inoculation most often occurs at the time of surgical repair. CoNS also are the most common cause of prosthetic valve endocarditis, accounting for 25% to 40% of all such cases. The pathogenesis is believed to involve contamination at the time of surgery, with subsequent formation of an abscess at the valvular ring.[123–125]

Although some cases of CoNS endocarditis are caused by the intrinsically pathogenic *S. lugdunensis,* most are caused by *S. epidermidis.*[121,123–125] Therefore, the course of CoNS endocarditis typically is indolent, sometimes evolving over several months, although acute onset with valvular destruction that requires surgical intervention also can occur.[121,126,127] Fever, the most common finding, is present in approximately 90% of patients. Other findings include splenomegaly, petechiae, and a new or changed murmur. Classic manifestations of bacterial endocarditis, including Osler nodes, Roth spots, Janeway lesions, and splinter hemorrhages, are uncommon. In practice, the initial blood culture isolation of CoNS in patients who later prove to have endocarditis frequently is dismissed.[128] Timely diagnosis, therefore, requires a high level of suspicion.

In neonates, CoNS endocarditis usually is right sided and tends to occur when the tip of an intravascular catheter is positioned in the right atrium.[129] Although the mortality associated with neonatal infective endocarditis caused by other pathogens is high, the outcome of CoNS endocarditis is more favorable. An important diagnostic clue to the presence of endocarditis in the neonate is persistent bacteremia despite removal of the catheter and appropriate antibiotic therapy, especially in the presence of thrombocytopenia. Distinguishing endocarditis from an infected intravascular thrombus at an extracardiac site sometimes is difficult. The diagnosis is confirmed by echocardiography, which reveals intracardiac lesions associated with a valve or the endocardial wall. Removal of the catheter is fundamental to cure.

Cerebrospinal Fluid Shunt Infections and Meningitis

In approximately 10% of cerebrospinal shunts placed in children, infectious complications occur within 24 months of the shunt's insertion,[130] and CoNS are the principal organisms implicated. *S. epidermidis* alone accounts for 60% to 75% of cerebrospinal fluid (CSF) shunt infections. Seventy percent of shunt infections occur within 2 months of placement, which suggests that in most cases seeding occurs at the time of surgery.[131] Because infection is associated commonly with shunt or catheter obstruction, signs and symptoms frequently reflect increased intracranial pressure, such as headache, vomiting, and depressed mental status. In addition, many patients have a low-grade fever. Examination of the CSF most often reveals modest pleocytosis, typically with an elevated protein concentration and sometimes with a slightly depressed glucose level. The Gram stain result is variably positive. In some patients the result of CSF analysis is completely normal; in these cases, repeated isolation of the same strain is required to establish causation.

Few data guide the optimal approach to an infected CSF shunt. Most practitioners remove the contaminated apparatus and eradicate infection with parenteral antibiotics; meanwhile the CSF is drained through a temporary external ventricular drain. A new internal shunt then is placed. Using mostly experiential data, a decision analysis concluded that this approach results in fewer deaths and treatment failures compared with strategies using antibiotics plus immediate shunt replacement or antibiotics alone.[132] In addition, some clinicians instill antibiotics directly into the ventricles through the drain,[133–135] but the benefits of this practice beyond those derived from systemic antibiotics and shunt removal are not known.

Isolated CoNS meningitis in the absence of an intraventricular foreign body has been reported in neonates, presumably as a result of undetected BSI.[106,136] One study described 10 infants with *S. epidermidis* meningitis who had unremarkable CSF white blood cell counts (mean, 6 cells/mm^3; range, 0 to 14) and normal glucose and protein concentrations.[136] In this series, no death or case of hydrocephalus secondary to meningitis was reported.[136] The possibility of more subtle, longterm sequelae was not assessed.[136]

Peritonitis Associated With a Peritoneal Dialysis Catheter

Infection remains the most common complication of peritoneal dialysis.[137,138] According to several studies the cumulative risk of peritonitis in patients undergoing continuous ambulatory peritoneal dialysis (CAPD) is approximately 60%.[138] *S. epidermidis,* the most common bacterial pathogen, accounts for roughly 40% of infections.[138] The most frequent symptoms of catheter-related peritonitis include abdominal pain, nausea, and vomiting. Fever is present in a minority of patients. The physical examination typically reveals abdominal tenderness, and in nearly all cases cloudy peritoneal fluid is present.

The criteria for the diagnosis of catheter-related peritonitis are not uniform from one study to another, but generally they include some combination of abdominal pain, peritoneal fluid with more than 100 neutrophils/mm^3, and a positive result on a peritoneal fluid culture.[138] In the absence of CoNS tunnel infection, antibiotic treatment without removal of the catheter usually is successful.[139,140] Effective regimens have included intraperitoneal, parenteral, oral, or intraperitoneal plus oral administration of antibiotics. Treatment failure requires retreatment or removal of the catheter.

Urinary Tract Infection

CoNS are an important cause of UTI, particularly in adolescent girls and young adult women.[141–145] *S. saprophyticus,* the species implicated most often, is identified readily in the clinical microbiology laboratory on the basis of its resistance to a 5-μg novobiocin disk.[146] *S. saprophyticus* UTI is almost always symptomatic, and it involves the upper urinary tract in approximately one half of cases. Sexual intercourse is an important risk factor for infection, presumably by facilitating the spread of bacteria from the urethra and periurethral area into the bladder. In one study nearly 70% of females with *S. saprophyticus* UTI gave a history of sexual intercourse within the 24 hours preceding the onset of symptoms.[142]

Other species of CoNS occasionally cause UTI, such as *S. epidermidis* and *S. haemolyticus.* In contrast to *S. saprophyticus,* these species most commonly produce disease in hospitalized patients, generally those with an indwelling urinary catheter. On occasion CoNS cause UTI in otherwise healthy children.[147]

Miscellaneous Infections

CoNS can cause a number of other infections, many described primarily in neonates. Pneumonia caused by CoNS occurs almost exclusively in ill premature infants. In general, the diagnosis is assigned when CoNS are isolated from blood of an infant with respiratory distress and a pulmonary infiltrate. A series by Hall and coworkers[56] identified 12 infants with hospital-acquired pneumonia among 27 with CoNS BSI; 9 of these 12 were intubated when a positive result on a blood culture and pulmonary infiltrate were identified, and 3 had been intubated previously. Neonates also can experience omphalitis and abscesses caused by CoNS.[148] Omphalitis is characterized by purulent discharge at the umbilical stump, along with erythema, edema, and tenderness in the periumbilical area. Abscess formation secondary to CoNS can occur at a variety of sites, but the most frequent are the breast and the scalp. Breast abscess is encountered most often during the second or third week of life and occurs more frequently in females. Scalp abscess usually is a complication of a scalp electrode used for fetal monitoring. In rare cases, CoNS can cause primary or secondary osteomyelitis in neonates, particularly in premature infants.[96,149] CoNS further has been implicated as a cause of hospital-acquired conjunctivitis in the NICU.[150]

In older children, CoNS are an important cause of endophthalmitis and keratitis,[151] which most frequently occur after intraocular trauma.[152] CoNS infections of the ocular surface also can result from prolonged use of contact lenses, including those used for orthokeratology.[153–155] Mediastinitis caused by CoNS can occur after median sternotomy for open heart surgery.[156] Additionally, BSI from CoNS may be potentiated by delayed sternal closure after surgery for congenital heart malformations, even in the absence of overt soft tissue infection.[157] CoNS infection also has been associated with a variety of implanted foreign bodies, including pacemaker wires, left ventricular assist devices, baclofen pumps, hemodialysis shunts, intravascular grafts, and prosthetic joints.[158–161]

Antibiotic Treatment

Resistance to penicillin, methicillin, and gentamicin is common among hospital-associated CoNS isolates.[56,113,162] Full resistance to vancomycin is rare but has been reported in isolates of *S. haemolyticus*.[163] Higher, “creeping” MICs of vancomycin for CoNS are a concern. Intermediate resistance to vancomycin has been observed in *S. epidermidis*, and the percentage of all clinical isolates of CoNS with a vancomycin or teicoplanin MIC of 4 μg/mL has increased with continued use of glycopeptides.[164–167] An adequate area under the plasma drug concentration–time curve (AUC) is difficult to achieve when the vancomycin MIC exceeds 1 μg/mL.

Despite these observations, vancomycin remains the antibiotic of choice for the treatment of suspected or proven CoNS infection. The need to initiate empiric use of vancomycin prior to receiving blood culture results is disputed. Septicemia from CoNS, even in the NICU population, usually is low grade,[168] and observational studies indicate no adverse effects on survival if vancomycin is withheld until infection has been proved. For example, in a multicenter study involving 348 NICUs that evaluated the need for empiric vancomycin use, the 30-day mortality rate was unaffected by delaying vancomycin therapy, even after the researchers had controlled for multiple potentially confounding variables.[169]

β-Lactam antibiotics should be used for CoNS septicemia when this course is supported by the results of antibiotic susceptibility tests. However, several caveats are noteworthy when considering the results of susceptibility tests. First, penicillin resistance in CoNS frequently is mediated by the production of β-lactamase, which is not always detected by microdilution methods.[170] Therefore all isolates that appear to be susceptible to penicillin or ampicillin should be tested specifically for the presence of β-lactamase.[170] Such testing should be done after exposure to oxacillin, which induces β-lactamase expression. Second, although each organism in a population of CoNS may have the *mecA* genetic determinant for resistance to methicillin (and other penicillinase-resistant β-lactams), only a small fraction express this phenotype under testing conditions.[171] Consequently, resistance to methicillin can be overlooked.[172] In vitro expression of resistance to methicillin is favored by testing a large inoculum and by incubation on a medium containing salt at 30°C to 35°C. Alternatively, PCR testing can be used to identify *mecA* directly in pure colonies. Third, routine susceptibility testing frequently indicates that isolates of CoNS resistant to methicillin are susceptible to cephalosporins; however, cross-resistance is extensive; for clinical purposes, therefore, all staphylococci that are resistant to penicillinase-resistant penicillins also should be considered resistant to cephalosporins.

Assuming rigorous testing, infections caused by penicillin-susceptible, β-lactamase–negative organisms can be treated with penicillin. For isolates resistant to penicillin but truly susceptible to the penicillinase-resistant penicillins, therapy with oxacillin or nafcillin is preferred. Vancomycin is the agent of choice only for CoNS resistant to methicillin and for patients allergic to penicillin. The combination of rifampin and clindamycin (if CoNS are susceptible) might be an alternative regimen for patients allergic to penicillin.[173]

In some situations, such as endocarditis or an infection related to an intraventricular CSF shunt, synergistic antibiotic therapy may be indicated. Synergy has been demonstrated in vitro for vancomycin or β-lactams in combination with rifampin and gentamicin (with isolates susceptible to each). For adults with CoNS, endocarditis involving a prosthesis, therapy with three drugs (a cell wall–active agent plus rifampin and an aminoglycoside) is recommended for the first 2 weeks; the patient then is treated for 4 more weeks with the cell wall–active agent and rifampin.[174] Combination chemotherapy is commonly used for native valve endocarditis caused by CoNS; however, whether the outcome is altered by therapy that includes one or more agents in addition to a β-lactam or vancomycin alone is uncertain.[127]

During the late 1990s and early 2000s, antibiotic alternatives to vancomycin were developed for the treatment of methicillin-resistant CoNS and other multidrug-resistant gram-positive pathogens. Daptomycin, a parenteral lipopeptide, has in vitro activity against most clinical isolates of CoNS,[175–177] but published experience on their use in pediatrics is limited.[178] Linezolid has activity against most isolates of CoNS and other gram-positive bacteria,[179,180] although epidemic clusters of clonally related, linezolid-resistant CoNS infections have been reported.[181,182] Unlike other agents used to treat methicillin-resistant CoNS, linezolid is available in both a parenteral and an oral preparation[183]; the latter allows convenient, effective home therapy in selected patients.

Prevention

Strict handwashing is of primary importance for minimizing the horizontal spread of CoNS. In addition meticulous skin preparation and surgical technique to limit intraoperative bacterial contamination are fundamentally important for minimizing infection related to foreign bodies.

Percutaneously inserted catheters impregnated with broad-spectrum antimicrobial agents (specifically silver sulfadiazine plus chlorhexidine or minocycline plus rifampin) have been tested in adults for their ability to reduce catheter-associated BSIs (CLABSIs) caused by CoNS and other pathogens. Although meta-analyses assessing these devices' ability to prevent catheter infections have been positive,[184] controversy remains about their effectiveness.[185,186] The consensus opinion recommends the use of such catheters only when other prevention measures have failed.[187]

Antibiotic-impregnated CSF shunts also are available.[188–190] Meta-analyses, mostly of single-center studies,[191,192] repeatedly have supported their effectiveness, indicating that they reduce the rate of infection by approximately 50%. Another analysis indicated a favorable cost-benefit ratio for their use under most conditions.[193] However, one of the meta-analyses[192] documented an increased risk of infection caused by methicillin-resistant *S. aureus* and gram-negative bacilli associated with placement of these shunts, even though the study demonstrated an overall reduction in CSF shunt infections.

The use of prophylactic antibiotics during the implantation of a foreign body has not been studied well, and the benefits of this practice remain uncertain. Studies on the addition of vancomycin to hyperalimentation fluid in neonates to reduce the incidence of CoNS CLABSI indicated efficacy,[194,195] but the risk of promoting vancomycin resistance outweighs the risk of CoNS BSI, even in very low birth weight infants. A stronger case has been made for the use of antibiotic lock to reduce the incidence of CLABSI. The advantage of this strategy is that a high concentration of antibiotic can be instilled and allowed to dwell in the catheter, permitting penetration of the biofilm, and then removed. At least two meta-analyses have examined multiple randomized trials that tested the effectiveness of antibiotic lock solutions in reducing infection in a variety of catheter types in adults and children. These studies indicated a significant reduction in CLABSI compared with participants whose catheters were infused only with anticoagulant.[196,197] Several studies have evaluated the effectiveness of a lock solution composed of 70% ethanol, which has broad activity against gram-positive and gram-negative bacteria and fungi, in preventing CLABSI.[198,199] Although mostly retrospective in design, these analyses reported a statistically detectable reduction in the incidence of infection in catheters in place for longer than 1 week.[198–201] Several important aspects of prophylactic antibiotic and ethanol lock strategies remain incompletely defined, including the effects on the catheter's integrity of prolonged exposure to the solutions, and the ideal dwell time; for example, when this strategy is used in infants, dwell time (even if short) can result in frequent episodes of hypoglycemia.[202,203] However, in older children who require life-sustaining CVCs and who have experienced multiple CLABSIs despite other measures, lock strategies may be considered beneficial overall.[187]

During the first decade of the 2000s, several programs successfully promoted “best practices” to reduce CLABSIs, which resulted in a reduction in CoNS infections. “Bundles” of best practices were constructed based on published evidence and expert consensus. Most programs promoted hand hygiene[204] and used two sets of bundles, one for catheter insertion and one for catheter maintenance.[205–207] In many instances the results were dramatic. In the program adopted by 103 adult ICUs in Michigan, catheter-associated BSIs were reduced 82% within 3 months, a level that was sustained over the subsequent year.[208] In the National Children's Hospital Association's collaborative intervention in pediatric ICUs, CLABSIs dropped from 5.4 per 1000 line-days to a sustained rate of 3.1 per 1000 line-days.[207] In the initial Vermont Oxford Network (VON) program implementing best practices in NICUs, the incidence CLABSI fell from 26.3% before intervention to 20.9% after intervention.[209] Subsequently, VON collaborative groups have refined methods to reduce CLABSIs and demonstrated further reductions.[210] In one large U.S. neonatal center, interventions to reduce CLABSIs coupled with the promotion of hand hygiene resulted in the near-eradication of CoNS infection for several consecutive years.[211]

Other Coagulase-Negative Micrococcaceae

The family Micrococcaceae includes the occasional human pathogens *Micrococcus* species and *Rothia mucilaginosa,* among other species.[21] As are CoNS, these organisms are nonmotile, nonspore-forming, gram-positive cocci that grow as irregular clusters. Traditionally, micrococci and staphylococci have been grouped together based on their similar cellular morphology and catalase production. However, the two genera differ considerably in amino acid content, and complete genetic analyses have confirmed only a distant relationship.[21] Organisms formerly belonging to the genus *Micrococcus* have been divided into six separate genera, including *Micrococcus* (which includes the species *M. luteus*), *Kocuria, Kytococcus, Nesterenkonia, Dermacoccus,* and *Arthrobacter*. The micrococci are normal residents of the skin and usually are not considered pathogenic. Occasionally micrococci, particularly those derived from the species *M. luteus,* can cause serious disease. In general, micrococcal infections occur in people who have an indwelling medical device and an associated underlying condition, such as CLABSI in leukemia, peritonitis in CAPD, CSF shunt infection, and endocarditis in patients with prosthetic valves. Micrococci also are common culture contaminants, and assessment of their significance can be difficult. Most isolates are susceptible to a wide range of antibiotics, including penicillin, methicillin, vancomycin, gentamicin, and erythromycin. However, because resistance to a variety of antibiotic classes has been reported, vancomycin is the preferred agent for empiric therapy.

R. mucilaginosa (formerly known as *Staphylococcus salivarius* and later as *Micrococcus mucilaginosus* and then *Stomatococcus mucilaginosus*) is differentiated from organisms in the genera *Micrococcus* and *Staphylococcus* by absent or weak catalase activity and failure to grow in a nutrient medium supplemented with 5% sodium chloride. *R. mucilaginosa* likely is underreported as a human pathogen because it can be mistaken for other microorganisms. When weakly catalase positive *R. mucilaginosa* can be confused with CoNS or micrococci, and when catalase negative with streptococci. Traditionally believed to be an organism with low virulence, *R. mucilaginosa* now is recognized as an opportunistic pathogen that can cause BSI, meningitis, pneumonia, endocarditis, and peritonitis.[212–217] *R. mucilaginosa* also has been implicated in skin and soft tissue infections in children.[216] Most affected children have leukemia or a solid tumor and profound neutropenia.[215,216] Other risk factors for infection include the presence of a CVC, valvular heart disease, CAPD, and intravenous drug abuse. *R. mucilaginosa* is a normal resident of the mouth and upper respiratory tract; oral mucositis, dental surgery, and head and neck surgery have been reported to predispose to infection. The clinical course of *R. mucilaginosa* infection often is characterized by prolonged fever and a slow response to antibiotic therapy. Occasionally, fulminant infection and fatality have occurred.[212,215,216] Based on the limited reported cases, *R. mucilaginosa* appears to be susceptible uniformly to vancomycin, and most isolates also are susceptible to penicillin, ampicillin, oxacillin, cefazolin, imipenem, clindamycin, tetracycline, erythromycin, and rifampin.

Key Points

Staphylococcus epidermidis and Other Coagulase-Negative Staphylococci (CoNS)

Microbiology

- Coagulase-negative gram-positive cocci that grow in irregular clusters
- More than 50 species and subspecies have been identified; 15 are normal human flora.
- Most reside on skin, but also are present on mucosa of the upper respiratory, gastrointestinal, and genitourinary tracts.

Pathogenesis

- Gain entrance through a disruption in the skin or mucosal barrier, such as occurs with a surgical procedure or placement of a device or a prosthesis
- Principal pathogenic characteristics are propensities to adhere to prosthetic surfaces and to form biofilm.
- Do not produce exotoxins; infections usually indolent

Clinical Syndromes

- Bloodstream infection, usually originating from a contaminated intravascular catheter

- Endocarditis, especially in the presence of a prosthetic valve
- Infection related to cerebrospinal fluid shunt
- Infection related to peritoneal dialysis catheter
- Community-associated urinary tract infection caused by *S. saprophyticus*, and healthcare, catheter-associated infection caused by multiple species
- Particularly prevalent in premature infants, in whom infection is less commonly associated with instrumentation than in older children and adults

Treatment

- Some community-associated strains remain susceptible to semisynthetic penicillins and cephalosporins.
- Most hospital-associated strains are methicillin resistant and require use of vancomycin.
- Removal of infected prosthetic material depends on its location, composition, and clinical factors.

Classification of Streptococci

David B. Haslam, Joseph W. St. Geme III

The genus *Streptococcus* is among the most diverse of bacterial genera. It consists of more than 50 species, and classification has been the source of considerable confusion.[1] Until recently, classification was based entirely on external characteristics of the organisms. Some features of the initial classification scheme remain useful to the clinician, such as patterns of hemolysis and serotype. Molecular methods have refined and clarified relationships among the diverse streptococcal species.[2,3] It is noteworthy that a variety of gram-positive catalase-negative cocci belonging to other genera often are erroneously referred to simply as "streptococci" (Box 117.1). The biochemical differentiation and clinical features of these genera are discussed elsewhere (see Chapter 124).

Box 117.1

Clinically Relevant Genera Constituting the Gram-Positive Catalase-Negative Cocci

Streptococcus	*Gemella*
Enterococcus	*Lactococcus*
Leuconostoc	*Abiotrophia*
Pediococcus	*Granulicatella*
Aerococcus	

The earliest subdivision of the genus *Streptococcus* was based on the ability to lyse sheep red blood cells.[4] β-Hemolytic streptococci produce complete hemolysis on sheep blood agar and cause the formation of a transparent ring around each colony. In contrast, α-hemolytic organisms produce partial red cell injury, induced by the release of hydrogen peroxide, which results in a green or grayish zone surrounding the colonies. When α-hemolytic organisms are grown under oxygen-depleted conditions, hydrogen peroxide is not formed, and colonies appear nonhemolytic. Nonhemolytic organisms are classified as γ-hemolytic. In order to avoid confusion in the classification of partially hemolytic streptococci, some investigators prefer that only β-hemolytic organisms be classified as hemolytic and that all others (including the α-hemolytic streptococci) be considered nonhemolytic.

Beyond the broad classification of streptococci based on hemolysis, Lancefield[5] subdivided these organisms on the basis of their reactivity with pools of antisera that now are known to recognize cell surface carbohydrates. Antigenically related strains are grouped alphabetically, A to H and K to V. Although the Lancefield grouping originally was used to differentiate the β-hemolytic streptococci, it should be noted that hemolysis and Lancefield serogrouping are not mutually exclusive. For example, group C streptococci can be α-hemolytic, β-hemolytic, or nonhemolytic.

Colony morphology commonly is used to differentiate streptococci further, and in some circumstances colony size takes precedence over other features in classification. Particularly notable in this regard are the viridans streptococci, an extremely heterogeneous group that includes organisms in most Lancefield groups (excluding A, B, and D) and with all patterns of hemolysis.[6] In general, a strain that produces minute colonies on solid agar is grouped with the viridans streptococci, regardless of its Lancefield reactivity or hemolysis.

When considered together, Lancefield grouping, hemolysis, and colony morphology enable a clinically useful subdivision of the genus (Table 117.1). For the most part the organisms of the Lancefield groups are β-hemolytic and associated with pyogenic infections. Organisms that cannot be assigned to a Lancefield group usually belong with the viridans streptococci; they generally are of lower virulence but may be associated with bloodstream infection, endocarditis, and a variety of diseases in a compromised patient.

Streptococcus pneumoniae is now grouped among the viridans sptreptococci based on its close genetic and phenotypic relatedness to the mitis group of organisms. *S. pneumoniae, S. mitis,* and *S. oralis* are difficult to distinguish using molecular testing methods.[7]

TABLE 117.1

Classification of Streptococci Most Commonly Associated With Human Disease

Lancefield Group[a]	Species	Hemolysis	Most Common Human Diseases
A	*Streptococcus pyogenes*	β	Pharyngitis, skin infection, wound infection, necrotizing pneumonia, conjunctivitis, postinfectious glomerulonephritis and rheumatic fever
B	*Streptococcus agalactiae*	β	Neonatal septicemia, meningitis, osteomyelitis, pneumonia
C[b,c]	*Streptococcus dysgalactiae* subsp. *equisimilis*	β	Wound infection, cellulitis, endocarditis, epidemic pharyngitis, pyogenic arthritis
	Streptococcus equi subsp. *zooepidemicus*	β	Septicemia, nephritis
D	Enterococci *Enterococcus faecalis* *Enterococcus faecium* Nonenterococcal species *Streptococcus bovis*	γ	Neonatal septicemia, intestinal and peritoneal infection, urinary tract infection, opportunistic infection
G[b,c]	*Streptococcus dysgalactiae* subsp. *equisimilis*	β	Puerperal infection, skin and wound infection, endocarditis, pyogenic arthritis
Not groupable[d]	*Streptococcus pneumoniae*	α	Pneumonia, otitis media, sinusitis, meningitis
	Other viridans streptococci *Streptococcus mitis* *Streptococcus salivarius* *Streptococcus anginosus* group *Streptococcus mutans* group *Streptococcus vestibularis* *Streptococcus parasanguis*	α[e]	Endocarditis, septicemia, dental infections, intravascular catheter–related infection

[a] Serogroups E, F, H, and K through V are rarely associated with human infections.

[b] Other group C and group G streptococci are unusual causes of human infections.

[c] *Streptococcus equi subsp. equisimilis* can have other Lancefield antigens, including groups A, G, and L.

[d] Minute, colony-forming organisms of Lancefield groups C, D, and G are included with the viridans streptococci.

[e] Occasional viridans streptococci are nonhemolytic, and others are β-hemolytic.

Other features commonly used to subdivide the streptococci are production of streptolysin-O and streptokinase, susceptibility to bacitracin and optochin, production of acetoin upon metabolism of glucose (Voges-Proskauer test), ability to grow in 6.5% sodium chloride, and ability to metabolize bile esculin or various carbohydrates. (These features are discussed in the other chapters of this section.)

With the advent of molecular techniques, the classification of streptococci underwent reanalysis. On the basis of genomic analysis, the more than 50 species constituting the genus *Streptococcus* have been subdivided into seven species groups that largely parallel the groupings produce by phenotypic methods (Fig. 117.1 and Table 117.2).[2,8] Classification based on genetic relatedness is most useful for the viridans streptococci because phenotypic classification of these organisms is particularly confusing and problematic (see Chapter 121).

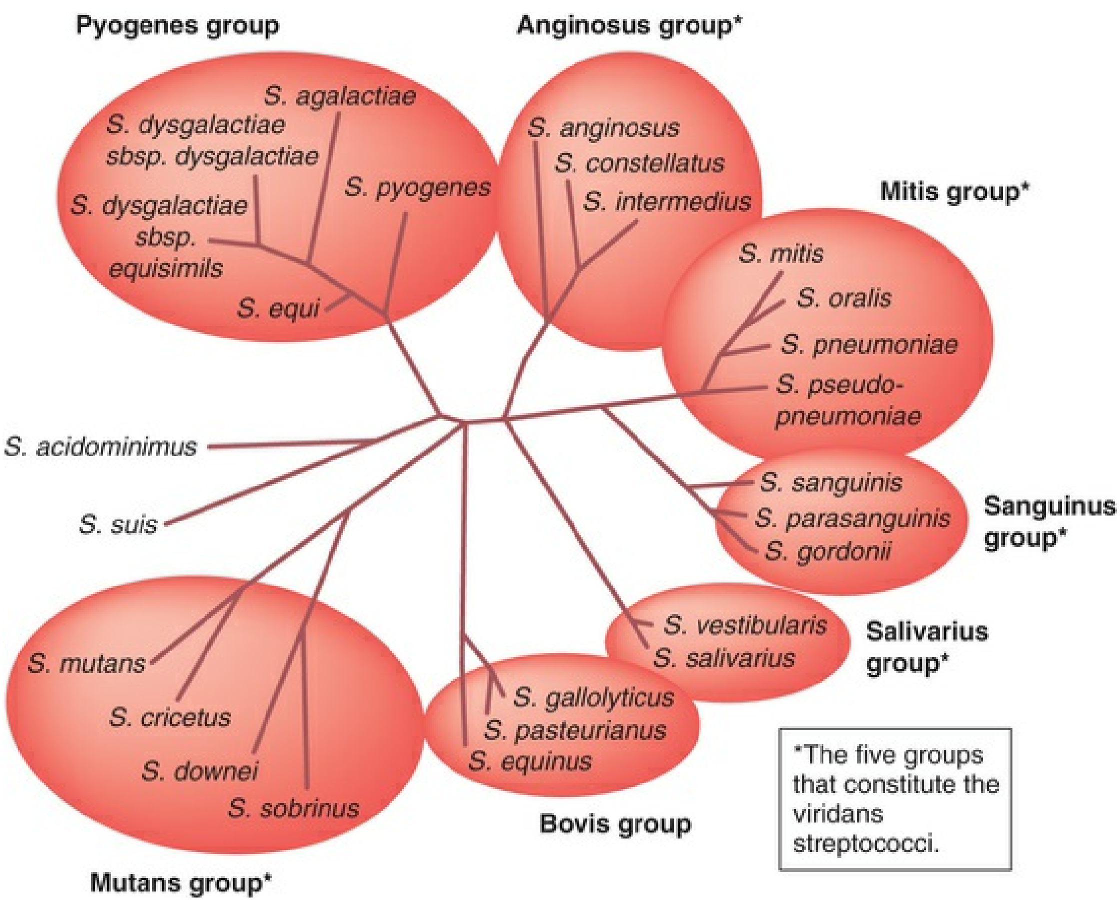

FIGURE 117.1 Schematic diagram of the phylogenetic relationship and classification of *Streptococcus* species. Intraspecis distances are not shown to scale.

TABLE 117.2

Clinically Relevant Organisms Constituting Seven Species Groups in the Genus *Streptococcus*

Group	Species Included
Pyogenes	*Streptococcus pyogenes* *Streptococcus agalactiae* *Streptococcus dysgalactiae subsp. dysgalactiae* *Streptococcus dysgalactiae subsp. equisimilis*
Mitis	*Streptococcus pneumoniae* *Streptococcus mitis* *Streptococcus oralis*
Sanguinis	*Streptococcus sanguinis* *Streptococcus parasanguinis* *Streptococcus gordonii*
Salivarius	*Streptococcus salivarius* *Streptococcus vestibularis*
Anginosus	*Streptococcus anginosus* *Streptococcus constellatus* *Streptococcus intermedius*
Mutans	*Streptococcus mutans*

Bovis	*Streptococcus gallolyticus* *Streptococcus pasteurianus* *Streptococcus equinus*

Streptococcus pyogenes (Group A *Streptococcus*)

Victor Nizet, John C. Arnold

Group A *Streptococcus* (GAS) is synonymous with *Streptococcus pyogenes*, the only species in this group of β-hemolytic streptococci. GAS is one of the leading pathogenic bacteria that infect children and adolescents, and it is associated with a wide spectrum of infections and diseases. Worldwide more than 600 million cases of GAS pharyngitis ("strep throat") and more than 100 million cases of GAS pyoderma are estimated to occur annually.[1] Although uniformly and exquisitely susceptible to penicillin and many other antimicrobial agents, GAS infections continue to present formidable clinical and public health challenges. The vast majority of GAS infections have a short duration and are relatively benign; however, invasive disease can be fulminant and life threatening. GAS also differs from other pyogenic bacteria in its potential to produce delayed, nonsuppurative sequelae, such as poststreptococcal acute glomerulonephritis (PSAGN) and acute rheumatic fever (ARF), after uncomplicated infections.

The importance of GAS infections in the United States was reinforced at the close of the 20th century by the appearance of severe, invasive GAS infections (e.g., streptococcal toxic shock syndrome [STSS] and necrotizing fasciitis) with high morbidity and mortality.[2] On the global scale, GAS is an important cause of morbidity and mortality primarily in less developed countries, causing more than 500,000 deaths per year.[1]

Description of the Pathogen

Microbiology

GAS is a gram-positive coccoid-shaped bacterium that grows in chains, producing small white to gray colonies with a clear zone of β-hemolysis on blood agar. It is distinguished from other groups of β-hemolytic streptococci by a group-specific polysaccharide (Lancefield antigen) in the cell wall.[3] Serologic grouping by the Lancefield method is precise, but group A organisms can be identified more readily by any one of a number of latex agglutination, coagglutination, or enzyme immunoassay procedures.

GAS can be subdivided into more than 100 immunologic serotypes by the M-protein antigen on the cell surface and by the fimbriae (hairlike fuzz) that project from the outer edge of the cell. Classically, typing of the surface M protein relied on the available polyclonal antisera, but this technique has been supplanted by a contemporary molecular approach that applies the polymerase chain reaction and deoxyribonucleic acid (DNA) sequencing of the 5′ variable region of the *EMM* gene encoding the M protein (http://www.cdc.gov/ncidod/biotech/strep/strepindex.htm). More than 200 distinct M genotypes have been identified using *EMM* typing, and a good correlation has been established between known serotypes and *EMM* types.[4,5]

M serotyping or genotyping has been valuable for epidemiologic studies; particular GAS diseases tend to be associated with certain M types. The M types commonly associated with pharyngitis rarely cause skin infections, and the M types commonly associated with skin infections rarely cause pharyngitis. A few of the “pharyngeal” strains (e.g., M type 12) have been associated with PSAGN, but far more of the “skin” strains (e.g., M types 49, 55, 57, and 60) have been considered nephritogenic. A few pharyngeal serotypes, but no skin strains, have been associated with ARF. However, evidence suggests that rheumatogenic potential does not depend solely on the serotype, but rather is a characteristic of specific strains within several serotypes. Certain GAS M types are more strongly associated with invasive disease, including M1, M3, M6, M12, M18, and M28. A globally disseminated clone of the M1 serotype has been the leading cause of severe invasive GAS infections, such as necrotizing fasciitis and STTS, over the past 3 decades.[6]

The GAS cell is a complex structure. In rapidly dividing strains (e.g., young cultures, epidemic strains), the cell is covered with a hyaluronic acid capsule that gives the colonies a mucoid or water drop appearance. Microscopic fimbriae protrude from the cell surface into the hyaluronic capsular layer, promoting the adherence of GAS to epithelial cells and extracellular matrix proteins. The fimbriae are composed of a surface-anchored, M protein that adopts a coiled-coil structure, which is closely associated with lipoteichoic acid polymers.[7] GAS are now recognized to express surface pili, corresponding to the classic "T antigen" used in earlier serologic typing schemes.[8] Roughly half of GAS strains display the capacity to opacify mammalian serum, through the activity of the surface-anchored serum opacity factor (SOF) protein, which binds to apolipoproteins to displace high-density lipoprotein (HDL) to form lipid droplets.[9]

The group A carbohydrate, encoded by the *gac* operon, comprises 40% to 50% of the dry weight of the GAS cell wall. The carbohydrate, a polymer of rhamnose units with side chains of *N*-acetyl-glucosamine, is responsible for its group (e.g., A) specificity.[3] As with other gram-positive species, a peptidoglycan polymer provides thickness and rigidity for the cell wall, consisting of glycan strands cross-linked by peptide bridges. M protein, pilus antigen, SOF, and other surface proteins are covalently attached to the GAS cell wall by recognition sequences in their C-terminal regions that interact with an anchoring enzyme called sortase.[10]

GAS produces and releases a large number of biologically active extracellular products into the surrounding medium. Some of these are toxic to human and other mammalian cells. Streptolysin S (SLS) is a small, oxygen-stable toxin responsible for β-hemolysis on blood agar; streptolysin O (SLO) is an oxygen-labile, cholesterol-dependent toxin related to staphylococcal α-hemolysin. Both SLS and SLO injure cell membranes, not only lysing red blood cells, but also damaging other eukaryotic cells and membranous subcellular organelles.[11] SLO is antigenic, whereas SLS is not. Streptococcal pyrogenic exotoxins (SPEs) are secreted factors that can act as superantigens and trigger T-lymphocyte proliferation and cytokine release.[12] GAS expresses a broad-spectrum cysteine protease, SpeB, which has multiple host targets; various specific peptidases that cleave host chemokines and complement factors; and several nucleases. GAS also produces bacteriocins, which are low molecular weight proteins that can kill a variety of other gram-positive bacteria, and thus may play a role in the promotion of infection or the persistence of colonization.[13]

GAS quorum sensing and virulence gene expression are controlled by the interplay of several transcriptional regulatory systems.[14–16] These include the two-component control of virulence system (CovR/S), which regulates 10% to 15% of the GAS genome, including its hyaluronic acid capsule synthesis operon, and the stand-alone Mga regulator, which controls expression of M protein and nearby virulence factor genes. Genome sequencing has shown that bacteriophages have played an important role in the evolutionary genetics of GAS, including the transfer of genes that encode antibiotic resistance, SPEs, and other virulence determinants.[17]

Pathogenesis and Virulence

GAS induces serious human disease by at least three mechanisms: suppuration, as in pharyngitis and pyoderma; toxin elaboration, as in STSS; and immune-mediated inflammation, as in ARF and PSAGN.[18] No complete explanation is available for the predilection of certain body sites for GAS infection, nor for the ability of certain M-type strains to produce pharyngitis and of others to produce pyoderma.

The first step in the pathogenesis of GAS disease in humans is successful colonization of the upper respiratory mucosa or skin. A large number of adherence factors for epithelial cells and extracellular GAS have been described, including lipoteichoic acid, M protein, pili, and fibronectin- or laminin-binding proteins, including Sfb1, SOF and Lbp.[19] The formation of a GAS biofilm facilitates persistence in humans.[20] Both M protein and fibronectin-binding proteins are important for subsequent endocytotic uptake of GAS into respiratory epithelial cells.[19] This process of intracellular invasion allows GAS access to a privileged intracellular niche, and it represents a proximal step in the pathogenesis of systemic infection.[21]

The propensity of GAS to produce serious infection in otherwise healthy children and adults defines the pathogen's ability to resist innate immune clearance mechanisms that normally prevent microbial dissemination.[22] For example, when GAS gains access to deeper tissues through cellular invasion or a break in epithelial integrity, it deploys specific peptidases that cleave and inactivate the neutrophil chemoattractants interleukin-8 and complement factor 5a. Likewise, SpeB can degrade the host's immunoglobulins and cationic antimicrobial peptides.

M protein is a multifaceted immune resistance factor that promotes GAS resistance to opsonophagocytosis through multiple mechanisms, including the binding of fibrinogen, complement inhibitory factor H, host antimicrobial peptides, and the Fc region of immunoglobulins.[23,24] M protein is essential to virulence in animal models, and immunization with M protein provides strong protection against infection with a type-specific GAS strain. During invasive infection, significant quantities of M protein are released from the cell surface by proteolysis; these can form a proinflammatory, clotlike complex with human fibrinogen, leading to uncontrolled neutrophil activation, vascular leakage, and toxic shock symptomatology.[25,26] M protein also collaborates with the GAS virulence factor streptokinase to bind host plasminogen to the GAS surface; this generates plasmin activity, effectively coating the bacterial surface with a powerful protease to facilitate tissue spread.[27]

The pore-forming toxins SLS and SLO are toxic to multiple host cell types, including macrophages and neutrophils, and therefore promote GAS tissue damage and resistance to phagocytic clearance. SLO in particular can induce accelerated apoptosis of immune cells[28] and inhibit neutrophil oxidative burst and neutrophil extracellular trap (NET) production.[29] The GAS hyaluronic acid capsule is not immunogenic, mimicking a common human matrix component, and cloaks opsonic targets on the bacterial surface from phagocyte recognition.[30] In the case of the highly invasive, globally disseminated M1T1 GAS clone, hyperinvasive forms bearing mutations in the CovR/S two-component regulator arises in vivo under innate immune selection, leading to upregulation of capsule and other key virulence determinants.[31] Specific virulence determinants present in the hyperinvasive M1T1 clone include the phage-encoded DNAse Sda1, which allows GAS to escape killing in DNA-based NETs, and the serum inhibitor of complement (SIC), which binds and inactivates terminal complement components and host defense peptides.

The SPEs are a family of more than 15 bacterial superantigens, including the bacteriophage-encoded SPE A and SPE C.[32] These superantigens induce antigen-nonspecific T-lymphocyte activation, suppress antibody synthesis, potentiate endotoxic shock, induce fever, promote the release of proinflammatory cytokines, produce reticuloendothelial blockade, and may contribute to the multiorgan failure characteristic of STSS.[33] In the U.S., STSS is commonly associated with infections caused by strains that produce SPE A.[33] Susceptibility to STSS appears to be related to the absence of antibodies to both M protein and superantigens, in addition to the presence of specific human leukocyte antigen (HLA) haplotypes.[34] The SPEs share homology with staphylococcal enterotoxins but not with staphylococcal toxic shock syndrome toxin-1.[12] SPE A and SPE C are responsible for the rash of scarlet fever, stimulating the formation of specific antitoxin antibodies that provide immunity against future scarlatiniform rashes, but not against subsequent GAS infections.

Immunologic Response

Although many GAS constituents and extracellular products are antigenic, protective immunity is type specific, mediated by opsonic anti-M-protein antibodies. These antibodies protect against infection with a homologous M type but confer no immunity against other M types.[35] Therefore, multiple GAS infections attributable to different M types are common during childhood and adolescence. Anti-M antibodies persist for years, perhaps for life, protecting against invasive infection but not against pharyngeal carriage.[36] A type-specific antibody may be transferred across the placenta from mother to fetus.[37] A type-specific antibody against M protein usually is not detectable until 6 to 8 weeks after infection[38];

therefore, its primary role may not be in the limitation or termination of active infection, but rather in the prevention of reinfection by the same serologic type. Opsonic type-specific antibodies do not appear after early and effective antimicrobial therapy.[39]

Humoral antibodies to specific streptococcal extracellular products such as antistreptolysin O (ASO) and anti-DNAse B can be demonstrated readily by neutralization assays. These assays have been particularly useful in allowing a more precise method of defining GAS infection in clinical and epidemiologic studies and in documenting the occurrence of a preceding GAS infection in patients suspected of having a nonsuppurative complication. The ASO assay is the most commonly used streptococcal antibody test. Because SLO is also produced by group C or group G streptococci, the test is not specific for GAS infections, and the response can be feeble in patients with streptococcal impetigo.[40] In contrast, the anti-DNAse B response is demonstrable after both skin and throat infections. Neutralizing antibody titers peak at 3 to 6 weeks for SLO and at 6 to 8 weeks for DNAse B. Antibody titers against GAS extracellular antigens reported by clinical immunology laboratories may vary. The upper limits of normal are higher for children than for adults, and these values, even for the same age group, are higher in some populations than in others.[41]

Epidemiology

GAS has a narrow host range; it is identified almost exclusively in humans and only rarely in other species.[42] GAS is highly communicable and can cause disease in individuals of all ages who do not have type-specific immunity. Disease in neonates is uncommon, probably because of placental transfer of maternal antibody. Significant differences exist between epidemiology of throat and skin infections due to GAS[43] (see chapters 27 and 68).

Severe invasive GAS infections had become uncommon in the U.S. and Western Europe during the second half of the 20th century. However, since the late 1980s a worldwide increase in severe invasive GAS infections has been seen.[44] The incidence of severe invasive GAS disease in industrialized societies (2 to 3 per 100,000 population) is similar in the geographically distinct regions of Europe, North America, and Australia.[45] This rate translates to about 10,000 cases of invasive GAS disease annually in the U.S.[46] However, rates of invasive disease in indigenous populations in Africa, the Asian subcontinent, and the Pacific islands typically are much higher[45]; rates as high as 82.5 per 100,000 have been reported in North Queensland, Australia.[47] Globally it has been estimated that at least 663,000 cases of invasive GAS disease occur each year, resulting in 163,000 deaths.[1]

The stratified squamous epithelium of the oropharynx and skin is the principal barrier against invasive GAS disease. GAS can gain access to sterile sites by means of direct inoculation after an injury that breaches the mucous membranes or skin[46]; however, a substantial number of invasive streptococcal infections have no known site of entry.[48] Epidemiologic data suggest that the oropharynx is the primary site of origin for systemic GAS isolates; therefore, invasive disease is likely to occur as a result of transient bacteremia originating from the oropharynx, possibly as a result of direct tissue penetration by GAS.[48] Varicella is a particularly important risk factor for severe invasive GAS infections in previously healthy children.[49] Other risk factors more common in adults include diabetes mellitus, human immunodeficiency virus infection, intravenous drug use, and chronic pulmonary or cardiac disease.

Clinical Manifestations and Clinical Syndromes

GAS is a common cause of acute pharyngitis (see Chapter 27) (Fig. 118.1) and pyoderma (impetigo) (see Chapter 68) in children and adolescents. GAS also produces a variety of other infections of the respiratory tract, including otitis media, retropharyngeal abscess, peritonsillar abscess, sinusitis, and mastoiditis; infections of the skin and soft tissues (Figs. 118.2, 118.3, and 118.4), which include cellulitis, erysipelas, perianal cellulitis, vaginitis, and blistering distal dactylitis (see chapters 68, 74, and 75), and invasive diseases, including STSS (see Chapter 13), necrotizing fasciitis, septicemia, meningitis, pneumonia, empyema, peritonitis, puerperal sepsis, neonatal sepsis, osteomyelitis, suppurative arthritis, myositis, and surgical wound infections. In addition, GAS is the proven cause of two potentially serious nonsuppurative complications, ARF and PSAGN, and the possible cause of two other potential nonsuppurative complications, poststreptococcal reactive arthritis (PSRA) and pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAs) (discussed later in the chapter).

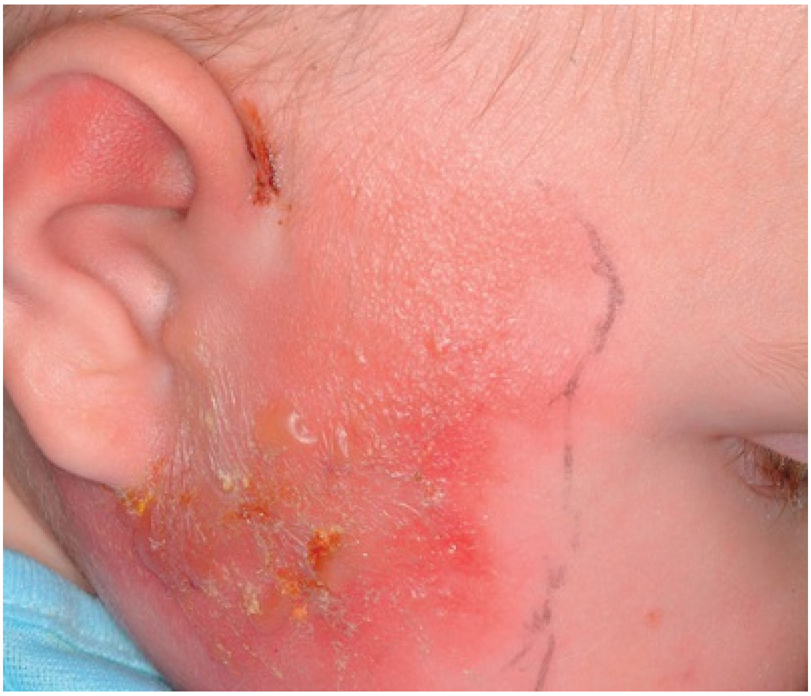

FIGURE 118.4 Toddler with erysipelas caused by group A streptococcus. (Courtesy of J.H. Brien©.)

Severe invasive GAS infection is defined as the isolation of GAS from a normally sterile body site; it includes three overlapping clinical syndromes. Cellulitis and bacteremia are the most common

GAS invasive diseases, each accounting for about 20% to 40% of invasive GAS disease in published epidemiologic reports.[50,51] Clinically, cellulitis is characterized by the acute onset of redness and inflammation of the skin, with associated fever, pain, and swelling. GAS bacteremia often triggers a rapid and robust proinflammatory cytokine response that results in a high fever, nausea, and vomiting. Cellulitis and bacteremia also can be preludes to the more serious invasive disease complications of necrotizing fasciitis and STSS.

The GAS "flesh eating disease," necrotizing fasciitis, is a devastating bacterial infection involving the skin, subcutaneous and deep soft tissues, and muscle. Necrotizing fasciitis involves rapid bacterial growth and spread along the fascial sheaths that separate adjacent muscle groups, breach of the fascial sheaths, and necrosis of adjacent tissues.[52] The pathogenesis of necrotizing fasciitis is complex and incompletely understood at the molecular level. However, the rapid tissue destruction and bacterial spread are thought to involve host and bacterial proteases (plasmin, SpeB), GAS pore-forming cytotoxins (e.g., SLO and SLS), and tissue-damaging enzymes released by host neutrophils in response to GAS cell wall components and superantigens.[52] A major risk factor for the development of necrotizing fasciitis is blunt trauma, which is suggested to result in increased vimentin expression that tethers circulating GAS to the injured muscle.[53] Primary varicella (chickenpox) in unimmunized children also is a well-documented predisposing condition.[49,54]

Invasive GAS infections also can result in STSS, a "cytokine storm" produced in response to GAS superantigens that substantially increases the risk of death.[50,55] GAS superantigens simultaneously engage major histocompatibility complex (MHC) class II molecules and T-cell receptor (TCR) β-chain variable regions, a molecular "bridging" that results in antigen-independent activation of large numbers of T lymphocytes. The resulting cytokine response by T lymphocytes (lymphotoxin-α, interleukin-2 [IL-2], interferon γ) and antigen-presenting cells (tumor necrosis factor [TNF]-α, IL-1β, IL-6) causes widespread organ dysfunction, disseminated intravascular thrombosis, and tissue injury. The result is an acute, rapidly progressive illness typified by high fever, rapid onset hypotension, and accelerated multisystem failure.[56] The magnitude of the STSS inflammatory response is closely linked to the severity of the disease. The sites where superantigens bind to HLA class II molecules are polymorphic, and strong epidemiologic and genetic evidence indicates that the host's MHC class II haplotype influences susceptibility to STSS.[34,57] Specific criteria for the diagnosis of STSS have been established (Box 118.1).[58]

Box 118.1

Definition of Streptococcal Toxic Shock Syndrome

Clinical Criteria

- Hypotension plus two or more of the following:
    - Renal impairment
    - Coagulopathy
    - Hepatic involvement
    - Adult respiratory distress syndrome
    - Generalized erythematous macular rash
    - Soft tissue necrosis

Definite Case

- Clinical criteria plus isolation of group A streptococci from a normally sterile site

Probable Case

- Clinical criteria plus isolation of group A streptococci from a nonsterile site

Working Group on Severe Streptococcal Infections. Defining the group A streptococcal toxic shock syndrome: rationale and consensus definition. JAMA 1993;269(3):390–391.

Laboratory Findings and Diagnosis

The clinical course of severe invasive GAS infections often is precipitous, requiring rapid diagnosis and initiation of the appropriate therapy. Although the initial clinical findings of STSS are nonspecific, a high index of suspicion is required, particularly in patients who have an increased risk (e.g., those with varicella). Pain out of proportion to superficial signs of infection can be a clue to underlying necrotizing fasciitis. Cultures of focal lesions are helpful in patients with skin or soft tissue involvement. Blood culture results can be positive in patients with sepsis without an apparent focus of infection. A complete blood count can show a relatively normal total leukocyte count, with a marked left shift to immature forms. The patient's blood pressure should be evaluated frequently. If necrotizing fasciitis is suspected, magnetic resonance imaging may be helpful in confirming the diagnosis; if the disease is present, histologic examination of excised tissue shows extensive necrosis, inflammation, hemorrhage, and thrombosis of small vessels.

Treatment

The initial management of a child or an adolescent with a severe invasive GAS infection includes hemodynamic stabilization and specific antimicrobial therapy to eradicate the GAS. When necrotizing fasciitis is suspected, prompt surgical drainage, debridement, fasciotomy, or amputation often is required. Patients with necrotizing fasciitis also need careful fluid and nutritional support and may require extensive skin grafting or other reconstructive surgery, as well as physical therapy. Fluid resuscitation is begun urgently and administered frequently; multiple boluses of fluid are required because of severe volume depletion and ongoing capillary leakage. When fluid resuscitation alone is insufficient to maintain adequate tissue perfusion, inotropic agents (e.g., dobutamine, dopamine, norepinephrine) should be considered.

Parenteral antimicrobial therapy should include agents active against GAS and *Staphylococcus aureus* until the results of bacteriologic studies are available. Once GAS has been identified, intravenously administered penicillin G (200,000 to 400,000 U/kg/day in four to six divided doses) is the drug of choice. A mouse model of streptococcal myositis suggests that clindamycin may be more effective than penicillin in eradicating GAS in severe invasive infections.[59] In addition, clindamycin inhibits protein synthesis and the production of important virulence factors (e.g., M protein, SPEs).[33] Therefore, many experts recommend intravenously administered clindamycin (40 mg/kg/day in three or four divided doses) in addition to penicillin.

Several case reports have described the use of intravenous immunoglobulin (IGIV) therapy in patients with severe invasive GAS infections. An observational cohort study conducted in Canada reported significantly reduced mortality among patients treated with IGIV compared with those who were not treated with IGIV.[60] However, this study had confounding factors that could have affected mortality data, including the use of historical controls and increased use of clindamycin among the patients treated with IGIV. A recent comparative observational study in Europe of 67 patients with streptococcal toxic shock syndrome suggested a therapeutic benefit of both IGIV (odds ratio, 5.6; P = .030) and clindamycin (odds ratio, 8.6; P = .007) with 28-day survival as the measured end point.[61]

Prevention

The only specific indication for longterm use of antibiotics to prevent GAS infection is for patients with a history of ARF or rheumatic heart disease (RHD). Mass prophylaxis generally is not feasible except to reduce the number of infections during epidemics of impetigo and to control epidemics of pharyngitis in military populations and in schools.

Measures to prevent the spread of GAS infections have variable effectiveness. The spread of throat or skin infection within a family often occurs before the index case is identified and isolated or treated. In epidemic situations, especially when cases of ARF or PSAGN occur, a culture survey and treatment of all individuals with positive culture results (mass prophylaxis) may be indicated.

Case reports of clusters of invasive GAS infections within a chronic care facility or among members of a single household have been published.[62] However, given the infrequency of these infections and the lack of a clearly effective chemoprophylactic regimen, the available data currently do not support a recommendation for routine testing for GAS colonization or for routine administration of chemoprophylaxis to otherwise healthy household contacts of people with invasive GAS disease. The Centers for Disease Control and Prevention recommend that healthcare providers inform household contacts of a person with invasive GAS disease about the clinical manifestations of pharyngeal and invasive GAS infections and emphasize the importance of seeking immediate medical attention if contacts develop such symptoms.[63]

Unfortunately, an effective vaccine to prevent GAS infection has yet to be developed. A major challenge is the great diversity of unique epitopes (more than 100) presented across GAS strains by the hypervariable N termini of the immunodominant surface M proteins. Another challenge is the data suggesting that GAS components, including the coiled-coil of the M protein and the GlcNAc side chain on the cell wall's group A carbohydrate antigen, could elicit antibodies that cross-react with the host's muscle or neural tissues, thereby triggering ARF. Proteomic and reverse vaccinology approaches have been used to explore conserved, surface-associated GAS protein antigens (e.g., pilus components, C5a peptidase, and fibronectin-binding proteins) as potential universal GAS vaccine candidates.[64] Two approaches have been tested in attempts to use the protective immunity of M protein without incurring the risks of molecular mimicry and autoimmune disease. One approach used a conserved, noncross-reactive, C-repeat region found in the carboxy-terminal of the M protein proximal to the cell wall. In the other approach, molecular techniques have been used to engineer genetically a highly complex multivalent M protein–based vaccine (e.g., 26-valent) containing a minimal B-lymphocyte epitope to optimize functional antibody responses.[65] Because GAS disease is a major cause of health inequality affecting indigenous children in Australia and New Zealand, the governments of the two countries recently formed the Coalition to Advance New Vaccines for group A *Streptococcus* (CANVAS) to assess several candidates and to fast-track development of a vaccine most likely to be safe, efficacious, and cost effective.[66]

Complications

Suppurative complications from the spread of GAS to adjacent structures were common before antibiotics became available. Cervical lymphadenitis, peritonsillar abscess, retropharyngeal abscess, otitis media, mastoiditis, and sinusitis still occur in children in whom the primary illness has gone unnoticed or treatment of pharyngitis has been inadequate. GAS pneumonia occurs occasionally. Nonsuppurative complications are considered in the following sections.

Acute Rheumatic Fever

ARF is an inflammatory disorder that commonly involves the joints and heart (and less commonly the brain and skin). It can develop as a complication of an untreated GAS upper respiratory tract infection. The association of GAS and ARF first was postulated based on parallels in peak age (5 to 15 years) and seasonal (winter/spring) incidence, coupled with the observation that outbreaks of GAS pharyngitis in closed communities (e.g., boarding schools and military bases) could be followed by outbreaks of acute ARF. Subsequent serologic studies documenting anti-GAS antibodies in patients with ARF provided further evidence. Clinical studies showed that the antimicrobial therapy that eliminates GAS from the pharynx also prevents initial attacks of ARF, and that longterm, continuous prophylaxis that prevents GAS pharyngitis also prevents recurrences of ARF.

Epidemiology

The incidence of ARF has declined substantially over the past 8 decades in the U.S. and other developed countries, a decline that began even before the advent of penicillin. However, ARF remains a major public health burden in much of the developing world. Currently at least 15.6 million people worldwide have RHD, and 282,000 new cases and 233,000 deaths annually are directly attributable to ARF or RHD.[1]

The incidence of ARF in some developing countries exceeds 50 per 100,000 children. Some of the highest incidence rates reported are in school-aged Pacific Islander children in New Zealand (80 to 100 per 100,000) and in aboriginal children in central and northern Australia (245 to 351 per 100,000).[67] In contrast, the most recent ARF incidence data for an industrialized country, obtained from the nonindigenous population of New Zealand, shows a rate of less than 10 per 100,000 children.[1] The prevalence of RHD in children aged 5 to 14 years is highest in subSaharan Africa (570 per 100,000), the Pacific Islander and indigenous populations of New Zealand and Australia (350 per 100,000), and south central Asia (220 per 100,000). In contrast, the prevalence in developed countries usually is about 50 per 100,000.[68] A dramatic outbreak of acute ARF occurred in the area of Salt Lake City, Utah, beginning early in 1985; more than 200 cases occurred in the first 4 years.[69] Other, smaller U.S. outbreaks have been reported in various communities and among recruits at military training centers, but these resurgences remained localized and did not lead to a nationwide increase in cases.

The observation that only a few patients with GAS pharyngitis subsequently experience ARF suggests that specific characteristics of the organisms, the host, and the environment contribute to this complication. Although all the risk factors have yet to be identified, certain potential factors have been described.

Experts have long suspected that various strains of GAS differ in the likelihood of subsequent ARF, and a limited number of M serotypes have been linked epidemiologically to outbreaks of ARF. Strains of certain rheumatogenic serotypes (e.g., types 1, 3, 5, 6, and 18), which were isolated infrequently during the 1970s and early 1980s, reappeared dramatically as causes of pharyngitis during the localized outbreaks of ARF in the mid-1980s. The marked decrease in ARF in the U.S. in recent decades has been correlated with replacement of rheumatogenic types by nonrheumatogenic types in childhood acute streptococcal pharyngitis.[70]

A genetic predisposition to ARF appears to be a factor.[71] Studies in twins have shown a higher concordance rate of ARF in monozygotic than in dizygotic twin pairs. Associations between susceptibility to ARF and HLA class II alleles, the B-lymphocyte alloantigen D8/17, or certain single-nucleotide polymorphisms for TNF-α or mannan-binding lectin genes, are under investigation; however, such an association has not been noted consistently in various populations. In one highly defined group with mitral valve disease, the collected data suggested that DRB1*0701, DR6, and DQB1*0201 confer susceptibility to ARF.[72]

Pathogenesis

The pathogenic link between a GAS infection of the upper respiratory tract and an episode of ARF has not yet been established definitively. Most attention has focused on the concept of autoimmunity based on molecular mimicry. This theory is supported by the latent period between GAS infection and ARF and by the observations of antigenic similarity between molecular constituents of GAS and several human tissues, including the heart, synovium, and basal ganglia. The sera of patients with ARF contain heart-reactive or myosin-reactive antibodies, frequently in high titers.[73] Studies of anti-GAS/anti-heart monoclonal antibodies from RHD have revealed that cardiac myosin, and GlcNAc, the immunodominant epitope of the group A carbohydrate antigen, are likely cross-reactive antigens involved in antibody deposition on the valve.[3,72] Early work had demonstrated the persistence of increased levels of anti–group A carbohydrate antibody in RHD and an association with a poor prognosis.[74] More recently, human T-lymphocyte clones also have confirmed cross-reactivity between cardiac myosin sequences and GAS M proteins.[75] Strikingly, immunization with purified recombinant GAS M6 protein is sufficient to induce autoimmune valvular heart disease in rats.[76]

Clinical Features

Because no single clinical or laboratory finding is pathognomonic for ARF, in 1944 T. Duckett Jones proposed guidelines to aid diagnosis of the disease and to limit overdiagnosis. The Jones criteria, as revised in 1992 by the American Heart Association (Box 118.2),[77] provide major criteria and minor criteria, in addition to the requirement for evidence (microbiologic or serologic) of recent GAS infection. The diagnosis of ARF is established according to the Jones criteria when a case fulfills two major criteria or one major plus two minor criteria and meets the absolute requirement of proof of antecedent GAS infection. Nonetheless, ARF can be overdiagnosed even with strict application of the Jones criteria.

Box 118.2

Jones Criteria for Diagnosis of First Episode of Acute Rheumatic Fever

Diagnosis

Diagnosis of acute rheumatic fever requires two major criteria or one major and two minor criteria, plus supporting evidence of antecedent group A streptococcal infection.

Major Criteria

Carditis

Polyarthritis

Chorea

Erythema marginatum

Subcutaneous nodules

Minor Criteria

Clinical findings: Fever; arthralgia

Laboratory finding: Elevated acute phase reactants (erythrocyte sedimentation rate or C-reactive protein); prolonged PR interval

Evidence Supporting an Antecedent Group a Streptococcal Infection

Positive throat culture or rapid antigen test for group A streptococcus
Or

Elevated or rising streptococcal antibody titer (e.g., antistreptolysin O, anti-DNAse B)

Under two circumstances the diagnosis of ARF can be made without strict adherence to the Jones criteria. Chorea may be the only manifestation of ARF. Similarly, indolent carditis may be the only manifestation in patients who first come to medical attention months after onset.

Major Manifestations

Migratory Polyarthritis.

Arthritis occurs in about 75% of patients with ARF and classically involves the larger joints, particularly the knees, ankles, wrists, elbows, or hips. In rare cases the spine or small joints of the fingers or toes can be affected. Inflamed joints and periarticular tissues generally are hot, red, swollen, and exquisitely tender; pain can precede other findings and can appear disproportionate to them. The migratory nature of the disease is most characteristic; a severely involved joint can become normal within 1 to 3 days without treatment, as one or more other large joints become similarly inflamed for up to 2 to 6 weeks. A dramatic response to even small doses of nonsteroidal anti-inflammatory drugs (NSAIDs) is characteristic; lack of a clear response should suggest an alternative diagnosis. Rheumatic arthritis is almost never deforming or associated with chronic changes.

Carditis.

Carditis occurs in about 50% to 60% of people with ARF. Carditis and resultant chronic RHD are the most serious manifestations of ARF, accounting for essentially all associated morbidity and mortality. Rheumatic carditis is a pancarditis, with inflammation of the myocardium, pericardium, and endocardium. Endocarditis (valvulitis), which manifests as one or more cardiac murmurs, is the hallmark of rheumatic carditis; myocarditis or pericarditis without evidence of endocarditis is rarely caused by ARF or RHD. The vast majority of cases consist of isolated mitral valvular or aortic and mitral valvular disease. Valvular insufficiency is characteristic of acute and convalescent stages of ARF, whereas valvular stenosis develops over years or decades. In developing countries, systematic echocardiographic screening suggests that the prevalence of chronic

RHD may be as high as 2% to 3%, 10 times the prevalence previously estimated by clinical screening.[78]

Acute rheumatic carditis usually presents as tachycardia and cardiac murmurs, with or without transient rhythm disturbances (reflecting myocardial involvement) or a friction rub (reflecting pericarditis). The characteristic murmur of mitral regurgitation is a high-pitched, apical, holosystolic murmur that radiates to the axilla. Moderate to severe rheumatic carditis can result in cardiomegaly and congestive heart failure with hepatomegaly and peripheral and pulmonary edema. Currently echocardiographic evidence of carditis without clinical support (i.e. auscultation of a new murmur) is neither a major nor a minor Jones criterion.

Chorea.

Sydenham chorea (St. Vitus dance) is a neurologic disorder that occurs in 10% to 15% of patients with ARF, often much later (up to 6 months) than other manifestations. A frequently subtle disorder of behavior and movement, Sydenham chorea is characterized by uncontrollable movements, emotional lability, hypotonia, poor school performance, and facial grimacing; symptoms often are exacerbated by stress and disappear during sleep.[79] The onset can be insidious, and symptoms can be present for several months before they are recognized. Diagnosis of Sydenham chorea is based on clinical findings, with or without supportive evidence such as high serum levels of antistreptococcal antibodies. Although the acute illness is highly distressing, chorea rarely, if ever, has permanent neurologic sequelae.

Erythema Marginatum.

Erythema marginatum is a rare but distinctive exanthem of ARF that is manifested by nonpuritic, macular lesions that are erythematous, serpiginous and have pale centers. A rash can occur primarily on the trunk and extremities, typically sparing the face; it is seen in less than 3% of patients with ARF.

Subcutaneous Nodules.

Less than 1% of patients with ARF develop firm, painless, subcutaneous nodules approximately 1 cm in diameter. These nodules can be palpated along the extensor surfaces of tendons near bony prominences. Subcutaneous nodules often correlate with significant RHD.

Minor Manifestations

The two minor clinical manifestations included in the 1992 revised Jones criteria are (1) arthralgia in the absence of the major criterion polyarthritis and (2) fever, typically 38.9°C or higher, that occurs early in the course of the illness. Two minor laboratory manifestations are (1) elevations of acute phase reactants, such as C-reactive protein and/or the erythrocyte sedimentation rate (which is usually >50 mm/hour); and (2) a prolonged PR interval on an electrocardiogram (first-degree heart block). Prospective studies have demonstrated that a prolonged PR interval alone does not constitute evidence of carditis nor predict longterm cardiac sequelae.

Evidence of Recent Streptococcal Infection

Supporting evidence of a recent GAS infection is an absolute requirement for the diagnosis of ARF, except with isolated Sydenham chorea. Because ARF develops 2 to 4 weeks after acute GAS pharyngitis, clinical signs of pharyngitis are no longer present, and the throat culture or rapid GAS antigen test result is positive in only 10% to 20% of cases. One third of patients recall no history of previous pharyngitis. Elevated or rising serum antistreptococcal antibody titers are the most reliable basis for diagnosis. If only the ASO level is measured, elevated titers (greater than 500 Todd units) are found in 80% to 85% of patients with ARF; 95% to 100% of such patients are identified if two additional antibody levels (e.g., anti-DNAse B, antistreptokinase or antihyaluronidase) are measured.

Differential Diagnosis

The differential diagnosis of ARF includes many infectious and noninfectious conditions associated with monoarticular or polyarticular arthritis (Table 118.1). Children with juvenile idiopathic arthritis (JIA) tend to be younger and usually have less joint pain relative to their clinical findings that do those with ARF. Spiking fevers, lymphadenopathy, and splenomegaly are more suggestive of JIA. The response to salicylate therapy is much less dramatic in JIA. Systemic lupus erythematosus (SLE) usually can be distinguished by the presence of antinuclear antibodies.

TABLE 118.1

Differential Diagnosis of Acute Rheumatic Fever

Arthritis	Carditis	Chorea
Juvenile idiopathic arthritis Systemic lupus erythematosus Serum sickness Sickle-cell disease Malignancy Gonococcal infection Reactive arthritis (e.g., *Shigella*, *Salmonella*, *Yersinia* spp.) Lyme arthritis	Kawasaki disease Viral myocarditis Viral pericarditis Infective endocarditis Mitral valve prolapse Congenital heart disease Innocent murmur	Huntington chorea Wilson disease Systemic lupus erythematosus Cerebral palsy Tics Hyperactivity Encephalitis

When carditis is the sole major manifestation of ARF, viral myocarditis, viral pericarditis, Kawasaki disease, and infective endocarditis should be considered. In general, the absence of a significant cardiac murmur excludes the diagnosis of ARF. Echocardiography can distinguish functional murmurs from murmurs caused by congenital heart defects. Patients with infective endocarditis can present with both joint and cardiac manifestations; usually positive blood culture results or associated findings (e.g., hematuria, splenomegaly, splinter hemorrhages) distinguish endocarditis.

Treatment

The management of ARF involves antibiotic and anti-inflammatory therapy, symptomatic treatment, and interventions to prevent future GAS infections. When the diagnosis of ARF has been established, a single intramuscular injection of benzathine penicillin or 10 days of orally administered penicillin or amoxicillin (or a macrolide, in penicillin allergy) is administered to eradicate GAS from the upper respiratory tract, regardless of the throat culture results. For patients who have definite arthritis and those who have carditis without cardiomegaly or congestive heart failure, salicylate therapy (50 to 75 mg/kg/day) should be given for 2 to 4 weeks, then tapered over the next 4 to 6 weeks. The response of ARF arthritis to salicylates is characteristically dramatic; no evidence indicates that other NSAIDs are superior. Patients with carditis and cardiomegaly or congestive heart failure often are prescribed corticosteroid therapy (e.g., 2 mg/kg/day for 2 weeks, with slow taper); a recent meta-analysis suggests that compared with aspirin alone, corticosteroids (or IGIV) reduce the risk of heart valve lesions in patients with ARF.[80] Supportive therapies for moderate to severe carditis include oxygen, fluid and salt restriction, diuretics, and angiotensin-converting enzyme inhibitors or digoxin. Bed rest for 2 weeks to 4 months, depending on the degree of carditis, usually is recommended. Because Sydenham chorea often occurs as an isolated manifestation after resolution of the acute phase of ARF, anti-inflammatory agents usually are not indicated. Patients may benefit from rest, limitation of external stimuli, and therapy with phenobarbital, haloperidol or chlorpromazine as guided by a pediatric neurologist.

Secondary Prevention and Prognosis

Because ARF frequently recurs with subsequent GAS infections, secondary prevention is required to avoid recurrences that increase the likelihood and severity of RHD. Secondary prevention requires continuous antibiotic prophylaxis, which should begin immediately after the full course of antibiotic therapy has been completed. Patients with carditis during the initial episode of ARF should receive antibiotic prophylaxis well into adulthood and perhaps for life. Other patients have a relatively low risk of carditis with recurrences, and antibiotic prophylaxis can be discontinued in these patients after 5 years or when they reach the age of 21 (whichever is later). The decision to discontinue antibiotic prophylaxis should be made only after careful consideration of the potential risks and benefits and the epidemiologic factors, such as the risk of exposure to GAS infections.

The regimen of choice for secondary prevention is a single injection of 1.2 million units of benzathine penicillin G every 4 weeks (Table 118.2). Continuous oral antimicrobial prophylaxis can be used in patients likely to adhere to the regimen. Prophylaxis using penicillin given twice daily or sulfadiazine given once daily is equally effective.

TABLE 118.2

Secondary Prevention of Rheumatic Fever (Prevention of Recurrent Attacks)

Agent	Dose
Benzathine penicillin G	1.2 million units IM every 4 weeks[a]
Penicillin V	250 mg PO twice daily
Sulfadiazine	0.5 g PO once daily for patients ≤27 kg; 1 g PO once daily for patients >27 kg
Erythromycin[b]	250 mg PO twice daily

[a] In high-risk situations, administration every 3 weeks is justified and recommended.

[b] For individuals allergic to penicillin and sulfadiazine.

IM, intramuscularly; PO, by mouth; U, units.

Adapted from Dajani A, Taubert Y, Ferrieri P, et al. Treatment of acute streptococcal pharyngitis and prevention of rheumatic fever: a statement for health professionals. Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young, the American Heart Association. Pediatrics 1995;96:758. Copyright American Academy of Pediatrics.

The prognosis for patients with ARF depends on the number and severity of clinical manifestations during the initial episode and whether recurrences were allowed to develop. In the absence of recurrent GAS infections, rheumatic fever does not reappear more than 8 weeks after the withdrawal of anti-inflammatory therapy. Approximately 70% of patients with carditis during the initial episode of ARF recover with no residual heart disease if they follow a prophylaxis regimen.

Acute Glomerulonephritis

Epidemiology

PSAGN was described by Richard Bright in 1836 as hematuria after scarlet fever. Unlike ARF, PSAGN occurs as a consequence of either GAS pharyngitis or pyoderma. PSAGN is primarily a disease of preschool and school-aged children; approximately 60% of patients are between 2 and 12 years of age. The actual incidence of PSAGN is difficult to determine because many cases are asymptomatic; however, PSAGN is by far the most common form of glomerulonephritis and acute renal insufficiency in children. Certain M types of GAS associated with pharyngitis (e.g., M1, M2, M3, M4, M12, and M15), in addition to certain M types associated with pyoderma (e.g., M49, M52, M55, M59, M60, and M61), are commonly associated with PSAGN and therefore are considered nephritogenic.[81] However, not all strains of a given M type are nephritogenic. Although PSAGN most often is a sporadic disease, it also can occur in epidemic forms. Concomitant presence of ARF and PSAGN is unusual in a population and rare in a patient.

Pathogenesis and Pathology

Although the pathogenic link between GAS infections and PSAGN has been clearly established, the mechanisms of renal injury have not been completely defined. However, considerable evidence suggests that PSAGN occurs when soluble immunoglobulin G immune complexes are deposited at the glomerular basement membrane, activating complement and the release of chemotactic factors that lead to infiltration by inflammatory cells. Whether the antigen in these complexes is a GAS antigen or a host-derived antigen that cross-reacts with antistreptococcal antibodies is not clear. Candidate GAS antigens for this process include glyceraldehyde-3-phosphatedehydrogenase (also known as "nephritis-associated" streptococcal plasmin receptor) and cysteine protease SpeB.[82,83] Because these proteins are present in virtually all strains of GAS, additional host factors are suspected to influence susceptibility, but studies of HLA antigen distribution have failed to identify a specific association with PSAGN.[84]

Although renal biopsy is rarely indicated for patients with PSAGN, biopsy can be helpful if hypertension, hypocomplementemia, heavy proteinuria, or renal insufficiency persists. The glomerular lesions of PSAGN can be proliferative, exudative, or both; typically glomeruli are involved diffusely. Electron microscopy reveals deposits consisting of immunoglobulin G and complement component C3, which usually are found in a subepithelial location during the first 3 to 6 weeks of the disease; the glomerular basement membrane usually appears normal.

Clinical Features

PSAGN typically occurs about 10 days after the onset of acute GAS pharyngitis or 3 weeks after the onset of GAS pyoderma. Edema (often periorbital) and hematuria are the clinical findings that usually bring patients with PSAGN to medical attention (Box 118.3). Approximately 30% to 50% of children with PSAGN have gross hematuria, which typically is described as "cola-colored" urine. Gross hematuria can persist for as little as a few hours or for as long as 2 weeks.

Box 118.3

Signs and Symptoms of Poststreptococcal Acute Glomerulonephritis (PSAGN)

Common Findings

Hematuria (microscopic or macroscopic)

Edema

Hypertension

Oliguria

Variable Findings

Systemic symptoms (fever, nausea, anorexia, lethargy, abdominal pain)

Uncommon Findings

Hypertensive encephalopathy (vomiting, headache, confusion, somnolence, seizures)

Anuria and renal failure

Congestive heart failure

Approximately 50% to 90% of children with PSAGN have hypertension. The severity of hypertension is highly variable, but systolic pressures greater than 200 mm Hg and diastolic pressures greater than120 mm Hg are not unusual. Most children with PSAGN also have evidence of circulatory congestion from the expansion of the intravascular fluid volume. Dyspnea, orthopnea, cough, or pulmonary rales may be present. Children with PSAGN also can have systemic symptoms, such as lethargy, anorexia, fever, and abdominal pain, but they seldom appear extremely ill. Occasionally a fulminant course can evolve, marked by severe oliguria, congestive heart failure, or hypertensive encephalopathy. Rare occurrences of reversible posterior leukoencephalopathy or autoimmune hemolytic anemia have been described.[85] Renal disease typically is self-limited, and spontaneous diuresis, loss of edema, and improvement in hypertension occur within 1 week.

Laboratory Findings

Virtually all children with PSAGN have microscopic hematuria, and 30% to 50% have gross hematuria. Evaluation of the urine shows pyuria and hyaline, granular, or red blood cell casts. Most children have proteinuria, and approximately 30% are in the nephrotic range, with protein loss greater than 2 g/m^2 per 24 hours.

During the initial 2 weeks of PSAGN, total hemolytic complement activity and C3 levels are depressed in almost all children. About one third of patients have modest elevations of blood urea nitrogen and creatinine. During the first week of PSAGN, elevations of circulating immune complexes are seen in most patients, and the quantity of these immune complexes correlates with the severity of the PSAGN. Patients with moderate to severe impairment of renal function can demonstrate metabolic acidosis, hyperkalemia, hyperchloremia, hyponatremia, hypoalbuminemia, or dilutional anemia. The best evidence of antecedent streptococcal infection is serologic; 90% to 95% of patients have elevations of ASO and/or anti-DNAse B.

Although antibiotic therapy does not affect the clinical course of PSAGN, therapy can eradicate the nephritogenic GAS strain that may still be present and thus reduce the risk of transmission to others. Penicillin is the antibiotic of choice; a macrolide is the preferred agent for patients allergic to penicillin. No immunosuppressant or antiinflammatory therapeutic agent has been shown to accelerate the resolution of renal lesions. Treatment consists primarily of supportive measures directed at complications of the disease. Occasionally the associated hypertension is so severe as to cause encephalopathy. Circulatory congestion can be severe and can lead to pulmonary edema and congestive heart failure. Although oliguria often is seen in children with PSAGN, anuria and renal failure are uncommon. Overall, the prognosis is favorable. More than 95% of children experience spontaneous and complete resolution of symptoms, edema, and renal dysfunction; urinalysis results are abnormal in less than 5% of patients 15 years after the acute episode.[86]

Prevention

In contrast to ARF, which can be prevented with antibiotic therapy of the antecedent GAS infection, no evidence indicates that PSAGN can be prevented once pharyngitis or pyoderma with a nephritogenic strain of GAS has occurred. Antibiotic treatment is given to limit transmission. During outbreaks of GAS pyoderma caused by nephritogenic strains, prophylactic administration of penicillin to children at risk may be beneficial.[87] Because recurrences of PSAGN are rare, longterm antibiotic prophylaxis after an episode is not indicated.

Pediatric Autoimmune Neuropsychiatric Disorders Associated With Streptococcal Infections

In 1998 investigators described a series 50 patients with childhood onset obsessive-compulsive disorder (OCD) and/or tics and suggested that these could arise as a result of a poststreptococcal autoimmune process.[88] The investigators coined the acronym PANDAS to denote *p*ediatric *a*utoimmune *n*europsychiatric *di*sorders *a*ssociated with *s*treptococcal infections. They proposed that, in response to GAS infection, this subset of patients with OCD and tic produced autoimmune antibodies that cross-reacted with neuronal tissues in the basal ganglia and associated structures, reminiscent of the autoimmune response implicated in similar clinical manifestations of certain patients with ARF and Sydenham chorea. Recently two prospective, blinded, multicenter cohort studies of matched pairs found no evidence of a temporal association between GAS infection and OCD/tic symptoms in children who met the published diagnostic criteria for PANDAS.[89,90] In another study, no correlation was seen between clinical exacerbations in these patients and serum antibodies cross-reactive with brain tissues.[91] In light of these findings, experts favor a broader concept (i.e., childhood acute neuropsychiatric symptoms [CANS]) and a broader treatment approach.[92]

Inaccurate diagnosis and treatment of PANDAS is widespread in the pediatric medicine community,[93] and new classification schemes can help delineate the risks for this particular subtype of OCD or tic disorder. Current data indicate that although PANDAS remains a hypothesis (perhaps applicable to a very select subset of patients), complicated interventions such as immune globulin or plasmapheresis may not be warranted.[90,94]

Poststreptococcal Reactive Arthritis

PSRA describes an entity in patients who had arthritis after an episode of GAS pharyngitis but lacked other major criteria for ARF. ARF peaks in early childhood (4 to 9 years), but PSRA has a bimodal distribution, with a first peak at 8 to 14 years and a second peak in early adulthood.[95] The arthritis of ARF classically develops 14 to 21 days after an episode of GAS pharyngitis and responds rapidly to NSAID therapy, whereas PSRA occurs about 10 days after GAS pharyngitis and does not respond readily to NSAIDs. In addition, the arthritis of PSRA is cumulative, persistent, and can involve large joints, small joints, or the axial skeleton, whereas the arthritis of ARF is migratory, transient, and usually involves only the large joints. All patients with PSRA have serologic evidence of a recent GAS infection. A few such patients may go on to develop valvular heart disease; therefore, they should be monitored carefully for carditis for several months. In contrast to the arthritis of ARF, PSRA can have a prolonged duration (median, 2 months) and can recur. Some physicians administer secondary prophylaxis to these patients for a period as short as 3 months and as long as 12 months; if carditis is detected, the patient should be classified as having had ARF and should continue to receive secondary prophylaxis. Unfortunately, validated diagnostic criteria for PSRA have yet to be established.[95]

Key Points

Group A *Streptococcus* and Clinical Syndromes

Epidemiology, Pathogenesis, and Immunity

- More than 600 million cases of pharyngitis and more than100 million cases of pyoderma annually worldwide.
- Rheumatic heart disease affects 15.6 million people worldwide
- Infections can be nonsevere and of short duration or rapidly invasive and fulminant.
- Unique among pyogenic bacteria in causing postinfectious, immunologically mediated diseases (acute rheumatic fever, acute glomerulonephritis)
- More than 100 distinct M-protein genotypes identified, which tend to be associated with infectious and nonsuppurative syndromes
- Genome sequencing shows that bacteriophages have been important in organism's evolutionary genetics (e.g., virulence determinants, and toxins).
- Pathogenesis of serious disease can occur by three mechanisms: suppuration, toxin elaboration, and immune-mediated inflammation.
- Expression of multiple specific virulence factors can lead to evasion of the patient's innate clearance response, uncontrollable proinflammatory response, damage to phagocytic cells, accelerated apoptosis of immune cells, inactivation of terminal complement components, superantigen-induced T-lymphocyte activation, and more.
- Opsonic anti-M-protein antibodies rise 6 to 8 weeks after infection and protect against M type-–specific invasive infection.

Clinical Manifestations

- Causes a wide spectrum of simple and complicated oropharyngeal and respiratory tract infections, skin and soft tissue infections, invasive infections, and toxin-mediated syndromes
- Necrotizing cellulitis, myositis, and fasciitis can be suspected when a seemingly minor skin or soft tissue infection is associated with disproportionate pain, hyperesthenia or hypoesthenia, local pallor, tenseness, and a blistering lesion.
- Proven cause of nonsuppurative acute rheumatic fever and acute glomerulonephritis (see text)

Treatment of Suppurative Infections

- Penicillin retains exquisite activity in vitro; no resistance to β-lactam antibiotics has been seen.
- Clindamycin usually is given in addition to a β-lactam for severe invasive or toxin-mediated disease to overcome the "Eagle effect" (loss of bactericidal capacity of β-lactam at a high density of bacteria/stationary growth phase) and to inhibit protein synthesis and virulence factors.
- Immune globulin intravenous (IGIV) therapy is reserved for severely ill patients with toxic shock syndrome.

Prevention

- Vaccine development has been thwarted by the hypervariability and diversity of surface M proteins and by potential immunologic responses that might cross-react with cardiac or neural tissue.
- Novel approaches explore the use of conserved or genetically engineered surface proteins.

Streptococcus agalactiae (Group B *Streptococcus*)

Morven S. Edwards, Carol J. Baker

The Pathogen and Pathogenicity

Streptococcus agalactiae is the species designation for Lancefield group B *Streptococcus* (GBS). Colonies appear on sheep blood agar as 3- to 4-mm, grey-white colonies with a narrow zone of β-hemolysis; organisms are gram-positive cocci. The group B–specific cell wall carbohydrate antigen is common to all strains, and a surface capsular polysaccharide (CPS) allows classification into types Ia, Ib, II, III, IV, V, VI, VII, VIII, and IX. A surface protein antigen, C protein, with *α* and β components, is common to all Ib strains, to 30% of type Ia strains, to 60% of type II strains, and to some type IV, V, and VI strains. Another surface component is a pilus that facilitates attachment to mucosal surfaces.

Pilus-like protein structures are found in all GBS strains of human origin. Antibodies to pili confer protection in experimental infection, which suggests that they play an important role in mediating attachment and invasion.[1,2] The *α* C surface protein mediates translocation across epithelial barriers; GBS also can use a paracellular route by transiently opening cell junctions.[3,4] The β-hemolysin/cytolysin forms pores that compromise epithelial and endothelial barrier function.[5,6]

High-virulence clones of GBS have emerged.[7] The hypervirulent clonal complex ST-17 of type III has a tropism for meninges and typically is found among invasive but not colonizing neonatal isolates. CPSs allow the organism to evade ingestion by host phagocytic cells. GBS suppresses phagocyte function and promotes bacterial survival by engaging host sialic acid–recognizing immunoglobulin superfamily inhibitory lectins.[8,9] Antibodies to CPSs are protective, and the risk for invasive infection correlates with low concentrations of antibodies to the infecting GBS CPS.[10]

The presence of GBS in the maternal genital tract at delivery is critical to early onset neonatal infection. Early onset infection occurs in 1% to 2% of infants born to mothers with GBS vaginal or rectal colonization at delivery who do not receive intrapartum antibiotic prophylaxis (IAP). Replication of organisms in association with maternal chorioamnionitis further enhances fetal/infant risk. The incidence of early onset disease is influenced by a number of factors (Table 119.1). The higher the genital inoculum, the longer the duration of exposure, and the greater the immaturity of the infant, the greater the risk of invasive neonatal infection.

TABLE 119.1

Pathogenesis of Early Onset Group B *Streptococcus* Infection

Feature	Comment
Strain virulence	Clonal virulence; capsule type (e.g., III), amount of capsule, hemolysin production, and certain surface components (e.g., sialic acid, C protein, hemolysin, pili, among others) enhance virulence by facilitating invasion and downregulating immune responsiveness
Inoculum size	Risk correlates with high density of maternal vaginal colonization
Premature rupture of membranes	Risk of infection increases with rupture of membranes before onset of labor
Preterm delivery	Risk correlates inversely with gestational age
Prolonged rupture of membranes	Risk increases when membranes are ruptured ≥18 hr before delivery
Maternal bacteriuria due to group B *Streptococcus* during pregnancy	Risk increases because bacteriuria correlates with dense maternal genital colonization, premature rupture of placental membranes, and preterm delivery
Serum concentrations of immunoglobulin G (IgG) to colonizing CPS type	Risk correlates inversely with levels of maternal serum IgG to the capsular polysaccharide of colonizing strain

As in early onset infection, low concentrations of antibody to type III CPS are found uniformly in sera obtained during the acute phase of illness from infants with later or very late onset infection. A viral infection preceding development may alter epithelial surfaces in a way that promotes entry of GBS into the bloodstream. Extended hospitalization, as is required by very low birth weight infants, enhances risk of healthcare exposure to GBS, if hand hygiene is not optimal.

Epidemiology

Depending on the culture method used and the population studied, GBS can be isolated from the maternal genital or lower gastrointestinal tract in 15% to 40% of pregnant women. When specimens are obtained from the rectum and lower vagina rather than the cervix, and when a selective antibiotic-containing broth medium is used rather than solid agar, colonization detection rates increase by 30% to 50%. Culture specimens obtained within 5 weeks before term gestation optimize the sensitivity in predicting colonization at delivery.

Neonates acquire colonization with GBS vertically, either in utero by the ascending route or at delivery. Heavy maternal colonization, intrapartum fever, African ethnicity, and lack of intrapartum antibiotic prophylaxis are associated with transmission.[11] Uninterrupted, the rate of vertical transmission of colonization from a mother colonized with GBS to an infant at delivery averages 50%. Infants born to mothers heavily colonized with GBS ($>10^5$ colony-forming units per milliliter [CFUs/mL]) or who have characteristics listed in Table 119.1 are at enhanced risk for invasive infection. Acquisition of colonization by infants can occur from the mother or other household contacts after hospital discharge. Whether late onset disease results from an exogenous source, such as breast milk, or from established colonization or both is unclear. The synchrony of recurrent disease in twins and the detection of GBS DNA in breast milk suggest that an enteral mode of acquisition can occur in some cases.[12]

The incidence of early onset GBS disease (within the first 6 days of life) has declined by 80% compared with the preprevention era baseline rate in 1993. In 2014 the incidence was 0.22 cases per 1000 live births.[13] Attack rates for early onset disease are related inversely to birth weight and can exceed 20 per 1000 live births in infants weighing less than 1000 g. However, because of the much larger number of births at term, most cases of early onset infections (~50%) occur in term infants. The incidence of late onset infection (7 to 89 days of age) has not been reduced through maternal IAP; in 2014 the incidence provisionally was 0.27 per 1000 live births.[13] GBS infections in infants 3 months of age or older occur primarily among those requiring prolonged hospitalization for complications of extreme prematurity.[14,15]

The CPS distribution of isolates causing early onset disease parallels that of organisms colonizing the maternal genital tract.[16] The CPSs that most commonly cause early onset disease, as reported by the Centers for Disease Control and Prevention (CDC), are Ia (30% of cases), III (28%), V (18%), and II (13%).[17] Recent reports indicate that type IV may be emerging as a cause of infant disease.[18] In late onset infections, CPS III accounts for 51% of cases, Ia for 24%, and V for 14%. Infections occur occasionally in epidemic clusters; the associated GBS types are similar to those that cause late onset disease.[19]

Clinical Manifestations

Early Onset Infection

Early onset GBS infection is associated commonly with maternal obstetric complications (Table 119.2).[20] The presenting signs, such as lethargy, apnea or bradycardia, and poor feeding, are indistinguishable from the signs of infections caused by other bacteria. Irritability and hyperthermia are noted more often in term than preterm infants (Table 119.3), and bacteremia without signs of infection occurs almost exclusively in term infants. Regardless of the age of onset and focus of infection, respiratory distress often occurs in infants with early onset infection. Radiographic findings can be consistent with pneumonia, respiratory distress syndrome, transient tachypnea of the neonate, or meconium aspiration.[15]

TABLE 119.2

Comparison of Early, Late, and Very Late Onset Group B

Feature	Early Onset	Late Onset	Very Late Onset
Age range	<7 days	7–89 days	≥3 mo
Median age at onset	1 day	37 days	Unknown
Maternal obstetric complications	Common	Preterm delivery	Varies
Frequency of gestation <37 wk	Frequent (~25%)	Frequent (~50%)	Typical
Usual clinical presentations	Septicemia (80%–85%) Meningitis (5%–10%) Pneumonia (10%–15%)	Meningitis (25%–35%) Bloodstream infection without focus (65%) Soft tissue, bone, joint infection, or pneumonia (5%–10%)	Bloodstream infection without focus (common) Bloodstream infection with a focus (occasional)[a]
Common capsular types	Ia, II, III, V	III (>50%), Ia, V	III, Ia, V
Mortality rate	3%–10%[b]	1%–6%	Low

[a] Includes peritoneum, urinary tract, skin and soft tissue, and central nervous system.

[b] <5% in term infants.

Hyperthermia	+	–
Healthy appearing	+	–

+++, most common; ++, commonly observed (25%–50%); +, occasionally observed (10%–25%); –, rarely observed.

The clinical syndromes commonly associated with early onset infection are bloodstream infection (BSI) without a focus (with shock in about 25% of cases), pneumonia, and meningitis.[21,22] Payne and colleagues[23] identified 6 features that predict a fatal outcome in early onset disease: (1) birth weight less than 2500 g, (2) absolute neutrophil count less than 1500 cells/mm^3, (3) hypotension, (4) apnea, (5) initial pH less than 7.25, and (6) demonstration of pleural effusion on initial chest radiograph.

Late Onset Infection

The median age of onset for late onset disease is 37 days.[20] Affected term infants usually have an unremarkable early neonatal course. BSI without a focus is the most common presentation, but meningitis occurs in about 30% of cases. Characteristic features are fever, poor feeding, and irritability; infants usually recover uneventfully with antimicrobial and supportive therapy. Infants with meningitis can have similar presenting features, but some have a fulminant onset and rapid progression. In these infants, the presenting features can include poor color, grunting, altered level of consciousness, apnea, or seizures. A number of presenting clinical or laboratory findings are associated with a fatal outcome or abnormal neurologic examination at hospital discharge for infants with GBS meningitis (Table 119.4).[24] Seizures at admission remain a significant risk factor for poor outcome in multivariate analysis.

TABLE 119.4

Features at Admission That Predict an Adverse Early Outcome for Infants With Group B *Streptococcus* Meningitis[a]

Feature	Comment
Need for pressors	Indicates advanced or overwhelming infection
Coma or semicoma	Indicates advanced or overwhelming infection
Seizures	Indicates cerebritis
Pallor	Surrogate for shock
Low cerebrospinal fluid (CSF) glucose	<20 mg/dL
Elevated CSF protein	≥300 mg/dL
High antigen content in CSF	Concentration of III-specific CPS in CSF >3 μg/mL

[a] See reference 24.

Several other foci of infection can occur in late onset disease, including osteomyelitis, arthritis, and cellulitis-adenitis syndrome. Osteomyelitis has an indolent presentation, with diminished mobility of an extremity or pain with motion that has been present for up to a month before diagnosis. Inflammatory signs are present occasionally but not reliably. The proximal humerus is the most frequent site in osteomyelitis; less frequently, the long bones of the lower extremities and flat or small bones are involved.[25]

The mean age at diagnosis of pyogenic arthritis is 20 days. The duration of signs of infection is usually several days, and the hip and knee joints are common sites of involvement. GBS cellulitis-adenitis syndrome usually is unilateral, involving facial or submandibular sites, although inguinal, scrotal, and prepatellar sites have been described.[26] Presenting signs include poor feeding, irritability, and fever. Affected infants typically have a BSI (>90% of cases), and aspiration of the involved soft tissue or lymph node often yields the organism. Abscesses can form, necessitating surgical drainage.

A number of less common or unusual foci of infection have been reported, including urinary tract infection with or without associated structural abnormalities, endocarditis, otitis media, necrotizing fasciitis, and others.[20] Isolation of GBS from a normally sterile body site should be considered indicative of invasive infection.

Very Late Onset Infection

In one report of GBS disease, 20% of the infants were older than 3 months.[15] For these infants, the terms *late onset, later onset,* or *very late onset infection* are applicable. Most of these infections occur among very low birth weight infants who require protracted hospitalization. Immature immune function and continued mucous membrane colonization probably contribute to susceptibility. Among term infants with a very late presentation, immunodeficiency, including human immunodeficiency virus infection, should be considered. BSI, without a focus or with the foci described previously for late onset infection, is the usual presentation (see Table 119.2). Among hospitalized infants, GBS infections associated with indwelling vascular catheters or necrotizing enterocolitis also have been observed.

Laboratory Findings and Diagnostic Tests

The diagnosis of invasive GBS infection is established by isolation of the organism from a sterile body site. Lumbar puncture is critical to diagnosing meningitis because as many as 30% of infants with meningitis have a sterile blood culture.[27] Early onset GBS infection can occur among infants whose mothers have a negative culture for GBS colonization, so a negative maternal GBS screen should not discourage infant evaluation for septicemia.[28] The finding of GBS in gastric or tracheal aspirates or in maternal amniotic fluid contents indicates infant exposure but does not define clinical illness. Abnormalities in the white blood cell (WBC) count, including leukopenia, neutropenia, or an increased ratio of immature-to-total neutrophils, often are found but have poor sensitivity. Sensitivity in predicting early onset GBS septicemia is improved if the WBC count is performed 6 to 12 hours after birth.[29]

Rapid antigen detection methods are not an appropriate substitute for cultures from blood or other normally sterile body fluid specimens. With currently available radiometric blood culture technology, antigen detection is required or indicated uncommonly, and only serum or cerebrospinal fluid (CSF) is recommended for testing.[30] Repeating antigen tests during therapy is not recommended. Diagnostic imaging for infants with meningitis is not useful for diagnosis or for managing the acute course of infection.

Treatment

The initial therapy for suspected GBS infection is ampicillin plus an aminoglycoside, typically gentamicin (Table 119.5). This regimen provides broad coverage for neonatal pathogens, and the combination is synergistic in vitro and in vivo for killing GBS. When GBS has been confirmed as the causative pathogen, a clinical response has been observed, *and* sterility of the bloodstream and CSF has been documented (by re-examination of the CSF, typically 48 to 72 hours after the start of therapy), treatment can be completed with penicillin G alone.

TABLE 119.5

Antibiotic Therapy for Group B Streptococcus Infections

Type of Infection	Antibiotic (Dose)	Expected Duration of Therapy

INITIAL EMPIRIC THERAPY[a]		
Suspected meningitis	Ampicillin (300 mg/kg/day) *plus* Gentamicin[a]	Until cerebrospinal fluid sterility *and* penicillin susceptibility documented
Suspected septicemia	Ampicillin (150 mg/kg/day) *plus* Gentamicin[b]	Until bloodstream sterility documented
DEFINITIVE THERAPY		
Bloodstream infection[c]	Ampicillin (150 mg/kg/day) *or* Penicillin G (200,000 U/kg/day)	Total antibiotic therapy of 10 days
Meningitis	Penicillin G (400,000–500,000 U/kg/day)	Total antibiotic therapy of 14–21 days
Arthritis	Penicillin G (200,000–300,000 U/kg/day)	Total antibiotic therapy of 2–3 wk
Osteomyelitis	Penicillin G (200,000–300,000 U/kg/day)	Total antibiotic therapy of 3–4 wk
Endocarditis	Penicillin G (200,000–300,000 U/kg/day)	Total antibiotic therapy of 4 wk

[a] Empiric therapy is always followed by definitive therapy.

[b] Dose as appropriate for postmenstrual age and days of life.

[c] Assumes that lumbar puncture to exclude meningitis has been performed and that cerebrospinal fluid has no detectable abnormalities.

Penicillin is the drug of choice. The suggested dosages and expected duration of therapy are summarized in Table 119.5. These dosages have proved safe and effective, even in premature infants. The rationale for use of the high doses recommended is that the minimal inhibitory concentration (MIC) of penicillin for GBS ranges from 0.01 to 0.6 μg/mL; the MIC is affected directly by inoculum size, and inoculum at sites of infection can be high. Antibiotic levels achieved in the blood or CSF with the suggested doses will exceed the MIC even when infection is associated with a high inoculum of a strain with an MIC at the upper range of susceptibility.

Reports from the United States and Japan describe point mutations in GBS penicillin-binding proteins that confer reduced susceptibility to penicillin and other β-lactam antibiotics.[31,32] Measured MICs are at the susceptibility threshold, but the clinical implications of these in vitro findings are unclear. In the usual circumstance, it is not necessary to determine the MIC and the minimal bactericidal concentration (MBC) of penicillin for the infecting GBS. Determination of GBS MIC and MBC should be considered when (1) a poor clinical or bacteriologic response to penicillin or ampicillin at the recommended doses occurs; (2) unexplained relapse or recurrence of infection occurs; and (3) infection occurs in an infant with congenital or acquired immunodeficiency.

Supportive care, directed at treating shock, correcting metabolic abnormalities, providing assisted ventilation, and controlling increased intracranial pressure, is paramount for optimizing the outcome of GBS infections. Administration of granulocyte colony-stimulating factor or an immunoglobulin preparation hyperimmune for GBS is clinically unproven.

Lumbar puncture should be considered before therapy for GBS meningitis is discontinued, usually at 14 days in uncomplicated cases. CSF findings that suggest inadequate therapy are a neutrophil value greater than 30% of the total WBCs and a protein level greater than 200 mg/dL. These findings are consistent with cerebritis or parenchymal destruction. It is our practice to continue therapy an additional week if CSF findings suggest inadequate resolution after 14 days of therapy and to reassess the CSF at 21 days of therapy. It is rarely necessary to continue treatment for meningitis longer than 3 weeks.

Contrast-enhanced imaging of the brain should be obtained before antimicrobial therapy is discontinued for infants with GBS meningitis because these findings can lead to prolongation of therapy.[33] Cranial imaging can reveal unresolved cerebritis or ventriculitis and can identify the rare infant with complications of subdural empyema or intracranial abscess. In addition, imaging identifies cerebrovascular complications that also can affect the prognosis.[34] All infants recovering from GBS meningitis should undergo diagnostic auditory brainstem response (ABR) test.

Special Considerations

Prognosis

Case-fatality rates range from 3% to 10% for early onset disease and from 1% to 6% for late onset disease. The risk of death for preterm infants is 8 times that for term infants for early onset and 3 times that for term infants for late onset disease.[17] Premature infants with septic shock who demonstrate periventricular leukomalacia often have neurodevelopmental sequelae. Among 53 term and near-term infants with GBS meningitis in the current era, infection was fatal in 6%, and 22% of survivors had neurologic impairment at hospital discharge, most commonly hypertonicity and persistent seizures.[24] Contemporary data suggest a 19% incidence of severe and a 25% incidence of mild-to-moderate neurologic sequelae among survivors of GBS meningitis.[33]

Recurrent Infection

The recurrence rate for early onset disease is approximately 1%. The mean age is 10 days at first episode and 42 days at recurrence.[35] No common risk factors or underlying conditions predict recurrence. The proposed causes include a persistent focus, inadequate dose or duration of therapy, reinfection with a second strain or type, and recurrent infection with the original strain in a nonimmune patient. Isolates analyzed from first and second GBS episodes often are genotypically identical.[12,36] The following guidance is offered for managing a recurrence: (1) confirm penicillin susceptibility of the isolate by MIC testing; (2) assess serum immunoglobulin and human immunodeficiency virus status; (3) treat empirically for 1 week longer than the usual course; and (4) consider oral rifampin therapy after completion of parenteral therapy in an attempt to eradicate mucosal colonization. The suggested dose for rifampin is 20 mg/kg/day for 4 days; this intervention has a success rate no higher than 50%, probably because the drug is bacteriostatic rather than bactericidal against GBS.[37] Evaluation for proof of eradication of colonization is not recommended because information is lacking for further management if colonization persists.

Prevention

IAP has proved efficacious for early onset disease. In 1986 Boyer and Gotoff[38] demonstrated that IAP administered to high-risk pregnant carriers of GBS reduced vertical transmission to infants, early postpartum febrile morbidity in women, and early onset sepsis. The American Academy of Pediatrics (AAP) published IAP guidelines in 1992.[39] A consensus approach was adopted in 1996 in which selection of women for IAP was based on antenatal cultures for GBS at 35 to 37 weeks' gestation or on the presence of a factor (without culture results) known to increase the risk for neonatal GBS septicemia.[40]

A large, population-based comparison demonstrating that culture-based screening was significantly more effective than risk-based intervention in preventing early onset GBS disease was reflected in the 2002 revised guidelines from the CDC (which were endorsed by the AAP and the American College of Obstetricians and Gynecologists) for prevention of perinatal GBS disease.[41–43] All pregnant women now are screened in each pregnancy for GBS at 35 to 37 weeks' gestation (vaginal and rectal sites are sampled, and specimens are processed in selective broth media). In women who previously delivered an infant with GBS disease or who experienced GBS bacteriuria during the current pregnancy, screening is not needed – IAP should be given. At the time of labor or rupture of membranes, IAP should be given to all pregnant women identified as GBS carriers except those undergoing a planned cesarean delivery before rupture of membranes and the onset of labor (Table 119.6). Prophylaxis with a β-lactam antibiotic (penicillin is preferred), given 4 or more hours before delivery, is highly effective for early onset disease prevention.[44] The risk-based approach should be used only when culture results are not available at the time of delivery.

TABLE 119.6

Indications and Nonindications for Intrapartum Antibiotic Prophylaxis to Prevent Early Onset GBS Disease

Intrapartum GBS Prophylaxis Indicated	Intrapartum GBS Prophylaxis Not Indicated
Previous infant with invasive group B *Streptococcus* (GBS) disease	Colonization with GBS during a previous pregnancy (unless invasive disease in previous infant or an indication for GBS prophylaxis is present for current pregnancy)
GBS bacteriuria during any trimester of the current pregnancy[a]	GBS bacteriuria during previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
Positive GBS in vaginal-rectal screening culture in late gestation[b] during current pregnancy[a]	Negative GBS in vaginal-rectal screening culture in late gestation[b] during the current pregnancy, regardless of intrapartum risk factors
Unknown GBS status at the onset of labor (culture not done, incomplete, or results unknown) and any of the following:	Cesarean delivery performed in a woman before onset of labor and with intact amniotic membranes, regardless of GBS colonization status or gestational age

• Delivery at <37 wk gestation[c] • Amniotic membrane rupture ≥18 hr • Intrapartum temperature ≥100.4°F (≥38.0°C)[d] • Intrapartum NAAT[e] positive for GBS	

[a] Intrapartum antibiotic prophylaxis is not indicated in this circumstance if a cesarean delivery is performed in a woman before onset of labor and with intact amniotic membranes.

[b] Optimal timing for prenatal GBS screening is at 35–37 weeks' gestation.

[c] Recommendations for the use of intrapartum antibiotics for prevention of early onset GBS disease in the setting of threatened preterm delivery are discussed in reference 44.

[d] If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

[e] NAAT testing for GBS is optional and might not be available in all settings. If intrapartum NAAT is negative for GBS but any other intrapartum risk factor (i.e., delivery at <37 wk gestation, amniotic membrane rupture at ≥18 hours, or maternal temperature ≥100.4°F [≥38.0°C]) is present, intrapartum antibiotic prophylaxis is indicated.

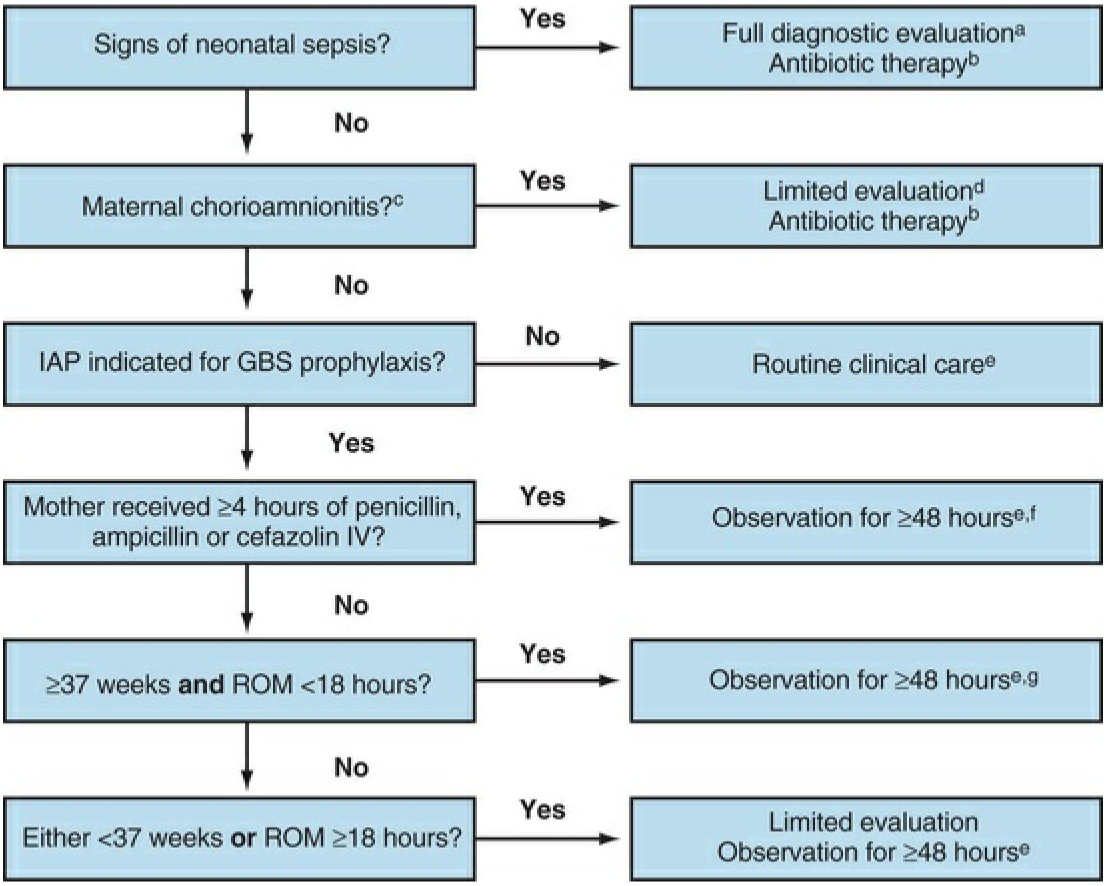
NAAT, nucleic acid amplification tests.

From Fairlie T, Zell ER, Schrag S. Effectiveness of intrapartum antibiotic prophylaxis for prevention of early-onset group B streptococcal disease. Obstet Gynecol 2013;121:570–577.

In 2010 the CDC updated the guidelines to be more comprehensive, but it reaffirmed the major prevention strategy – universal antenatal GBS screening and IAP for culture-positive and high-risk women. It also included new recommendations for (1) laboratory methods for identification of GBS colonization during pregnancy; (2) algorithms for screening and IAP for women with preterm labor and premature rupture of membranes; (3) an updtated prophylaxis regimen for women with a penicillin allergy; and (4) a revised algorithm for the care of newborns.[45] Options for GBS identification from vaginal and rectal swabs now include positive identifications from chromogenic media and identifications directly from antibiotic-containing broth. Nucleic acid amplification tests (NAATs), such as commercially available polymerase chain reaction assays, are allowed for screening after enrichment if laboratories have validated their NAAT performance and use quality controls. Implementation of an algorithm based on the CDC guidelines eliminated 25% of all early onset sepsis evaluations and achieved substantial cost savings at one center.[46]

The maternal IAP regimen should consist of intravenous penicillin G (5 million units initially, then 3 million units every 4 hours) until delivery. Intravenous ampicillin (2 g initially and 1 g every 4 hours until delivery) is an acceptable alternative. Women allergic to penicillin who do *not* have a history of anaphylaxis, angioedema, respiratory distress, or urticaria after administration of penicillin or a cephalosporin should receive cefazolin (2 g initially and 1 g every 8 hours until delivery). The definition of adequate IAP is receipt of an antibiotic (penicillin, ampicillin, or cefazolin) at least 4 hours before delivery.[45] All other agents, doses, or durations are considered inadequate for purposes of neonatal management. For high-risk women allergic to penicillin (anaphylaxis, angioedema, respiratory distress, or urticaria), clindamycin (900 mg every 8 hours until delivery) can be given if the colonizing GBS isolate has been documented to be clindamycin susceptible. Current data estimate that 30% of GBS isolates are clindamycin resistant. Early onset GBS has been documented in an infant with a clindamycin-resistant organism whose mother received IAP with clindamycin.[47] Vancomycin (1 g every 12 hours until delivery) is an alternative agent for women at high risk for penicillin allergy in whom clindamycin-resistant GBS has been isolated from screening cultures. Neither clindamycin IAP nor vancomycin IAP has been evaluated for efficacy in preventing early onset GBS neonatal disease.

The management of infants depends on a number of factors: the infant's clinical status; the presence or absence of maternal chorioamnionitis; the duration of penicillin, ampicillin, or cefazolin IAP before delivery, if indicated; the duration of membrane rupture, and the infant's gestational age. An algorithm of the recommended infant management that applies to all newborns is summarized in Fig. 119.1. If signs of sepsis are noted, a full diagnostic evaluation and empiric antibiotic therapy are indicated. If a healthy-appearing infant is born to a mother with chorioamnionitis, a limited evaluation (blood culture at birth and CBC at birth and/or at age 6 to 12 hours) is recommended, based on the infant's exposure through established maternal infection. Healthy-appearing infants born to a mother who received appropriate doses of intravenous penicillin, ampicillin, or cefazolin 4 hours or longer before delivery are observed in the hospital for at least 48 hours before discharge, unless signs of sepsis develop that prompt a full evaluation and initiation of antibiotic therapy. Infants with a gestational age of 37 weeks or older, and those born to mothers in whom membrane rupture occurred less than 18 hours before deliver and the duration of IAP was less than 4 hours before delivery, should undergo observation for 48 hours. Healthy-appearing infants whose gestational age is less than 37 weeks, and those born to mothers in whom membrane rupture occurred 18 hours or longer before delivery and who received IAP for 4 hours or longer before delivery, require a limited evaluation and observation for 48 hours. Exposure to antibiotics during labor does not change the clinical spectrum of GBS disease or the age of onset of clinical signs of early onset infection, should it occur.[48]



Signs of neonatal sepsis?

Either <37 weeks **or** ROM ≥18 hours?
Yes
Limited evaluation
Observation for ≥48 hours[e]

FIGURE 119.1 **Algorithm for prevention of early onset group B *Streptococcus* (GBS) disease among newborns. IAP, intrapartum antibiotic prophylaxis; ROM, rupture of membranes. [a]Full diagnostic evaluation includes a blood culture; a complete blood count (CBC), including white blood cell differential and platelet counts; chest radiograph (if respiratory abnormalities are present); and lumbar puncture (if patient is stable enough to tolerate procedure). [b]Antibiotic therapy should be directed toward the most common causes of neonatal sepsis; it should include intravenous ampicillin, with**

consideration of an aminoglycoside for synergy for GBS and coverage for other organisms (including *Escherichia coli* and other gram-negative pathogens) and should take into account local antibiotic resistance patterns. [c]Consultation with obstetrics providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are nonspecific. [d]Limited evaluation includes a blood culture (at birth) and CBC with differential and platelet counts (at birth and/or at 6 to 12 hours of life). [e]If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated. [f]If ≥37 weeks' gestation, observation may occur at home after 24 hours if other discharge criteria have been met, access to medical care is readily available, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until discharge criteria are achieved. [g]Some experts recommend a CBC with differential and platelets at age 6 to 12 hours. (Adapted from Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal infection: revised guidelines from CDC 2010. MMWR Morb Mortal Wkly Rep 2010;59[RR-10]:1–31.)

With the substantial reduction in early onset GBS infection achieved through implementation of IAP policies, the current national projection is 990 cases of early onset and 1050 cases of late onset GBS disease annually in the U.S.[13] Black infants remain at higher risk than white infants for GBS disease, possibly because of differences in access to prenatal care and rates of preterm births.[17] A further reduction in early onset disease might be realized by improving implementation of antibiotic prophylaxis and correcting errors in culture screening methods.[49]

Although IAP is a desirable interim approach, it results in the administration of an antibiotic to approximately 30% of women at delivery, and the emergence of antimicrobial resistance remains a concern.[21] Prevention of GBS invasive infections, irrespective of age of onset or presence of maternal risk factors, awaits the development of suitable vaccines. Candidate CPS-protein conjugate vaccines are in development, and maternal immunization to prevent infant disease should be cost-effective.[50] Once a vaccine has demonstrated efficacy, women of childbearing age could be immunized to protect their neonates against GBS. This model has proved successful in the prevention of tetanus, and it holds promise for application to perinatal GBS infection.[51]

Key Points

Diagnosis and Management of Group B *Streptococcus* (GBS) Infection

Microbiology

- Narrow zone of β-hemolysis on blood agar, and gram-positive cocci microscopically
- Grow readily in blood culture media and from normally sterile sites
- Polysaccharide capsule and pilus-like structures enhance virulence.

Epidemiology

- Colonizes lower gastrointestinal and genital tracts of one quarter to one third of men and women
- Major cause of invasive infection in infants <3 months of age
- Early onset infection rates have declined in association with implementation of maternal intrapartum antibiotic prophylaxis, whereas the late onset infection incidence has remained unchanged.
- Three GBS types (Ia, III, and V) account for the most invasive infections.

Diagnosis

- Suspect in young infants with signs of sepsis, meningitis, pneumonia, bone or joint, or skin and soft tissue infection
- Isolation of organism from blood or another normally sterile site is diagnostic.

Treatment

- Penicillin is the drug of choice; isolates are susceptible to β-lactams, vancomycin, and meropenem.
- Usual treatment duration is 10 days for bloodstream infection and 2 to 3 weeks for meningitis.

Prevention

- Intrapartum antibiotic prophylaxis given during labor to GBS-colonized women reduces early onset infection risk.
- Glycoconjugate vaccines in development offer potential for prevention of infection in pregnant women and young infants.

Enterococcus Species

David B. Haslam, Joseph W. St. Geme III

Historically enterococci, *Streptococcus bovis,* and *S. equinus* were grouped together as Lancefield group D streptococci. However, DNA hybridization studies have resulted in the reclassification of these organisms, and enterococci now are considered a separate genus (Table 120.1). This chapter focuses on enterococci; the nonenterococcal group D streptococci are discussed in Chapter 121.

TABLE 120.1

Clinical Significance of Enterococci and Group D Streptococci

Species	Association With Infection in Children
***ENTEROCOCCUS* SPECIES**	
Enterococcus faecalis	Relatively frequent
Enterococcus faecium	Infrequent but increasing
OTHER *ENTEROCOCCUS* SPECIES	Infrequent
E. durans, E. avium, *E. casseliflavus, E. dispar,* *E. flavescens, E. gallinarum,* *E. hirae, E. malodoratus,* *E. mundtii, E. pseudoavium,* *E. raffinosus, E. solitorius*	
NON-*ENTEROCOCCUS* SPECIES	Infrequent
Streptococcus bovis	
Streptococcus equinus	

Enterococci were recognized as part of the normal intestinal flora more than a century ago.[1] However, medical science's improved ability to support critically ill patients, including extremely premature infants, and the widespread use of antimicrobial agents have led to the emergence of enterococci as pathogens in human infection.[2]

Description of the Pathogen

Enterococci are gram-positive, facultatively anaerobic bacteria that grow as diplococci or in short chains. Most isolates are nonhemolytic on sheep blood agar, although some have α-hemolytic or β-hemolytic activity. Unlike other gram-positive, catalase-negative bacteria, the group D organisms grow at 45°C and can withstand temperatures up to 60°C. They can grow in bile; in addition, they hydrolyze esculin, a feature not found in other streptococci of the Lancefield groups (5% of viridans streptococci and most lactococci, aerococci, pediococci, and leuconostocs share this property).

Clinical laboratories often distinguish enterococci from nonenterococcal group D organisms on the basis of the enterococci's ability to grow in 6.5% sodium chloride. The PYR reaction (hydrolysis of L-pyrrolidonyl-P-naphthylamide) is also a rapid means of distinguishing enterococci from *S. bovis* and *S. equinus. S. pyogenes,* the only other PYR-positive streptococcus, is easily distinguished from enterococci by its positive reaction with group A antiserum and susceptibility to bacitracin. *Enterococcus faecalis* and *E. faecium* are common human pathogens that are distinguished from each other on the basis of carbohydrate fermentation (Table 120.2).

TABLE 120.2

Biochemical and Growth Characteristics of Clinically Significant Enterococci and Group D Streptococci

	Enterococcus faecalis	*Enterococcus faecium*	*Streptococcus bovis*
Bile esculin	+	+	+

Lactose	+	+	+
Starch	−	−	+

+, Most isolates demonstrate the characteristic; +/−, occasional isolates test positive for the characteristic; −, most isolates test negative for the characteristic. NaCl, Sodium chloride; PYR reaction, hydrolysis of L-pyrrolidonyl-P-naphthylamide.

Enterococci have several important virulence factors, including adhesive factors called Esp, aggregation substance, and ACE (a collagen-binding protein). Other virulence determinants include a cytolysin and degradative enzymes, such as gelatinase, hyaluronidase, and a serine protease. Many of these virulence factors are encoded on a pathogenicity island that is more commonly found among virulent than commensal isolates. The propensity of *E. faecalis* to cause endocarditis in adults may be related to surface carbohydrates that permit avid adherence to the endothelium of heart valves.[3] Once established on heart tissue, *E. faecalis* stimulates synthesis of fibrinogen, contributing to vegetation formation. Similarly, infection of the urinary tract may relate to the organism's ability to adhere to renal epithelial cells. The *E. faecalis* cytolysin, which is encoded by the pathogenicity island, has lethal activity against a broad range of eukaryotic and prokaryotic cells. This factor contributes to virulence in experimental models of endocarditis, peritonitis, and endophthalmitis.

Antimicrobial resistance allows the persistence and proliferation of organisms despite treatment with broad-spectrum antibiotics. The enterococci have a remarkable propensity to exchange genetic material, both as donor and recipient. Whole genome sequencing revealed that up to 25% of *Enterococcus* genetic material is composed of mobile or exogenously acquired DNA. The ability to transfer DNA, including vancomycin resistance genes, to other species is a major concern.

Epidemiology

Enterococci are ubiquitous inhabitants of the gastrointestinal tract of humans and animals. *E. faecalis* is the predominant organism and is found in the feces of more than 90% of adults. Nearly 50% of neonates are colonized with *E. faecalis* by 1 week of age. Colonization with *E. faecium* is less common but appears to be increasing in frequency; it is present in approximately 25% of adults. Although the gastrointestinal tract is the predominant habitat of enterococci, organisms also can be found in oral secretions and dental plaque, in the upper respiratory tract, on the skin, and in the vagina.

E. faecalis accounts for most enterococcal infections, which generally are presumed to arise from the patient's indigenous flora. Direct spread from person to person (i.e., by droplet or fecal-oral transmission) has not been considered an important means of transmission, although evidence of nosocomial transmission is growing.[4,5]

Clinical Manifestations

Most enterococcal infections occur in individuals in whom a surface physical barrier breaks down, such as in the gastrointestinal tract, the integument, or the urinary tract. Other factors associated with enterococcal infections in children are prolonged hospitalization, treatment with antibiotics, and a compromised immune system. In neonates, *Enterococcus* organisms commonly are associated with septicemia, whereas in older children and adults they are most commonly associated with bacteremia, intra-abdominal abscess, and urinary tract infection (UTI). Among hospitalized adults, enterococci account for approximately 10% of bloodstream infections (BSIs), and they are associated with mortality in one third of affected patients.[6]

Neonatal Infections

Enterococci account for up to 10% of all cases of neonatal BSI. The rate of enterococcal BSI fluctuates from year to year, but the incidence appears generally to be increasing, concomitant with the longer survival of extremely premature infants. These infections most commonly are caused by *E. faecalis* and much less commonly by *E. faecium*.

Two distinct syndromes of neonatal enterococcal BSI have been described. Early onset BSI (within 7 days of birth) manifests similarly to early onset group B streptococcal septicemia, although the former tends to be milder. Early onset infection most often occurs in full-term infants who are otherwise healthy. Late onset infection (after 7 days of age) is associated with risk factors such as extreme prematurity, presence of an intravascular catheter, necrotizing enterocolitis, or a recent surgical procedure. The symptoms of late onset disease are more severe than those of early onset disease; they include apnea, bradycardia, and deteriorating respiratory function. Focal infections, such as a scalp abscess or a catheter-related infection, also are common. Mortality rates range from 6% in early onset septicemia to 15% in late onset infections associated with necrotizing enterocolitis.[7] Enterococci cause approximately 5% of bacteremic episodes in previously healthy young infants who come to medical attention with a fever.[8]

Enterococcus is an occasional cause of meningitis. In neonates, in particular, meningitis usually occurs as a complication of BSI. Alternatively the organism can gain access to the central nervous system by means of contiguous spread, such as through a neural tube defect, a neurenteric cyst, an intrathecal injection, or a ventricular shunt placed for the management of hydrocephalus.[9] A noteworthy fact is that enterococcal meningitis can be associated with minimal abnormality of the cerebrospinal fluid.

Infections in Older Children

Enterococcal BSI generally is an infection of hospitalized children, and it is not limited to a particular age group.[10] Predisposing factors include an indwelling central venous catheter, gastrointestinal disease, immunodeficiency, cardiovascular abnormalities, and hematologic malignancy. Genitourinary disease is a frequent predisposing factor in adults, although less common in children. Children with community-acquired enterococcal infections generally are younger than 1 year of age. As in adults, BSI caused by *Enterococcus* spp. commonly is polymicrobial, probably reflecting the severity of underlying disease and the bowel as the source.

Enterococci rarely cause UTIs in healthy children, but they account for approximately 15% of nosocomially acquired UTIs in both children and adults. Placement of an indwelling urinary catheter is the major risk factor for a nosocomial UTI, and early removal of urinary catheters reduces the incidence of infection.[11] Enterococci also cause intra-abdominal abscesses after intestinal perforation; however, the significance of enterococci in these polymicrobial infections has been questioned because an antimicrobial regimen with poor activity against enterococci often is an effective treatment. Enterococci frequently are part of polymicrobial chronic infections in patients with neurologic deficits, pressure ischemic osteomyelitis, soft tissue necrosis. Enterococci cause up to 15% of cases of endocarditis in adults, but these organisms rarely infect the heart in children.

Treatment

Antimicrobial Resistance

Enterococci uniformly are resistant to cephalosporins, and they have at least a low resistance to other β-lactam agents. Unfortunately, high resistance to aminoglycosides and vancomycin is becoming increasingly prevalent. The antimicrobial resistance of *Enterococcus* spp. can be divided broadly into intrinsic and acquired forms.[12] In general, intrinsic resistance results from chromosomally encoded factors, whereas acquired resistance is carried on transposable elements (Box 120.1). In most cases of acquired resistance, plasmid-encoded factors are exchanged in a process mediated by sex pheromones. Receptive organisms respond to pheromones by aggregating, which facilitates subsequent conjugation and plasmid transfer. Occasionally, acquired resistance results from mutation of a chromosomal gene. Resistance of *E. faecium* generally is more common and significant than that of *E. faecalis* (Table 120.3).

Box 120.1

Antimicrobial Resistance of Enterococci

Intrinsic Resistance (Chromosomally Encoded)

Aminoglycosides (low-level resistance)

β-Lactams (especially semisynthetic penicillins and cephalosporins)

Clindamycin (low-level resistance)

Acquired Resistance

Aminoglycosides (high-level resistance)

Chloramphenicol

Erythromycin

Clindamycin (high-level resistance)

Fluoroquinolones

Penicillins (β-lactamase)

Tetracycline

Vancomycin

TABLE 120.3

Antimicrobial Susceptibility of *Enterococcus* Species

	Enterococcus faecalis (µg/mL)			*Enterococcus faecium* (µg/mL)		
Agent	**Range**	**MIC$_{50}$**	**MIC$_{90}$**	**Range**	**MIC$_{50}$**	**MIC$_{90}$**

β-Lactam Resistance.

Enterococci are highly resistant to cephalosporins and semisynthetic penicillins (e.g., nafcillin, oxacillin, and methicillin) and moderately resistant to extended spectrum penicillins (e.g., ticarcillin and carbenicillin). Ampicillin, imipenem, and penicillin are the most active β-lactam agents against enterococci; their minimal inhibitory concentrations (MICs) range from 1 to 8 µg/mL (see Table 120.3). Although the bactericidal activity of active β-lactams always is superior to that of vancomycin, the minimum bactericidal concentration (MBC) often is considerably higher, and tolerance to β-lactam agents (defined as an MBC to MIC ratio >32) is common. Any active drug can be insufficient if used alone for serious infections in which high bactericidal activity is desired. In rare cases, strains of *E. faecalis* produce a plasmid-encoded β-lactamase similar to that found in staphylococci. These isolates are completely resistant to penicillins; consequently, alternative agents or the combination of a penicillin plus a β-lactamase inhibitor is required.

Aminoglycoside Resistance.

All enterococci have an intrinsic low resistance to aminoglycosides (MIC of 8 to 250 μg/mL), which probably reflects poor transport of these antibiotics across the cell wall. Concomitant use of a cell wall–active agent, such as a β-lactam or a glycopeptide antibiotic to which the isolate is susceptible, improves the cell wall's permeability to aminoglycosides, resulting in synergistic killing.[13] High resistance, defined as an MIC greater than 2000 μg/mL, results from the modification of aminoglycosides through adenylation, phosphorylation, or acetylation. Strains that demonstrate high resistance (which usually are acquired nosocomially) are not affected by combination therapy comprising aminoglycosides plus cell wall–active antibiotics. It is noteworthy that some moderately resistant isolates also are not affected synergistically by this therapeutic combination.

Vancomycin Resistance.

Resistance to vancomycin among enterococci emerged during the past 2 decades and spread rapidly. The proportion of enterococcal infections caused by vancomycin-resistant organisms has reached approximately 30%.[14] Both high and moderate resistance have been described for *E. faecalis* and *E. faecium*. High resistance (MIC ≥64 μg/mL) can be transferred by means of conjugation and is usually plasmid mediated. The gene that confers high resistance vancomycin, *vanA*, encodes an inducible protein that creates a D-alanine:D-lactate ester, rather than the normal D-alanine:D-alanine linkage, in the cell wall. Vancomycin binds less avidly to the altered linkage and thus is unable to disrupt cell wall synthesis. Moderate resistance (MIC 8 to 32 μg/mL) results from D-alanine:D-lactate activity expressed from a transposable homologue of *vanA* known as *vanB*. Isolates that harbor the *vanB* gene are only moderately resistant to vancomycin because they have residual D-alanine:D-alanine linkages. Although most *vanB* isolates initially are susceptible to teicoplanin, resistance can emerge during therapy. Other vancomycin phenotypes exist, encoded by *vanC, vanD, vanE,* and *vanG* genetic elements, but these are less prevalent and generally do not result in high resistance.

Other Antibiotics.

Resistance of enterococci to almost all classes of antibiotics, including tetracyclines, macrolides, and chloramphenicol, has been described, and individual susceptibility testing must be performed when use of these antibiotics is considered. Despite the apparent susceptibility of enterococci to trimethoprim-sulfamethoxazole (TMX) in vitro, the drug has poor activity against the organisms in vivo because they efficiently scavenge thymidine and its precursors from blood and urine.

Options for treating vancomycin-resistant enterococci (VRE) infections are limited. Linezolid and daptomycin currently are the most reliable agents. Linezolid, an oxazolidinone, inhibits bacterial protein synthesis and is bacteriostatic against *E. faecium* and *E. faecalis.* Its MIC_{90} (i.e., minimal inhibitory concentration required to inhibit 90% of isolates) is 4 μg/mL or less against both species, including vancomycin-resistant isolates. Treatment with linezolid appears to result in the most favorable outcomes for enterococcal BSI in children.[15] However, resistance to linezolid among VRE isolates has been described and can develop during prolonged therapy. Studies in adults suggest that daptomycin treatment may be associated with improved outcomes.[16]

Daptomycin, the first lipopeptide antibiotic, has been approved for use in complicated skin infections. It disrupts the bacterial membrane through the formation of transmembrane channels, and it has bacteriostatic activity against both *E. faecalis* and *E. faecium.* Resistance to daptomycin has been reported among enterococci but remains rare.

Tigecycline and oritavancin have in vitro activity against VRE. Tigecycline, a tetracycline derivative, has been approved for use in complicated intra-abdominal and skin and soft tissue infections. Although it is bacteriostatic, tigecycline has not yet been approved for use against VRE; however, it has good activity in vitro against both vancomycin-resistant *E. faecalis* and *E. faecium* and likely will become a valuable therapeutic agent.[17]

Quinupristin-dalfopristin (Synercid) is a combination streptogramin antibiotic that inhibits bacterial protein synthesis at two different stages. The drug is active against many *E. faecium* strains, including those with high vancomycin resistance, but notably, it is inactive against *E. faecalis*. Quinupristin-dalfopristin, therefore, should not be used as the sole agent when gram-positive organisms are identified by Gram stain until culture results exclude the presence of *E. faecalis.*

Treatment Strategies

In an otherwise healthy patient, minor localized infections caused by enterococci generally can be treated with ampicillin alone. Antibiotics containing β-lactamase inhibitors (clavulanate or sulbactam) provide an advantage only with rare organisms that have high resistance because they produce β-lactamase. Most species are susceptible to nitrofurantoin and fosfomycin, and these agents are alternatives to penicillins for uncomplicated UTIs.

Severe systemic infections (e.g., BSI, endocarditis, and meningitis) usually are treated with combination therapy. Ampicillin plus an aminoglycoside has been the most common regimen for organisms susceptible to both. However, addition of an aminoglycoside can be associated with nephrotoxicity; this justifies caution in its use for an uncomplicated BSI caused by *E. faecalis*.[18] The combination of ampicillin and ceftriaxone often is used in cases of *E. faecalis* endocarditis, and it has shown equivalent efficacy to ampicillin plus an aminoglycoside in adults.[19] Vancomycin can be substituted for ampicillin for patients with immediate-type hypersensitivity to penicillin, but it should be used with another agent (typically an aminoglycoside) because its action alone is only bacteriostatic.

Infections caused by enterococcal strains with high resistance to aminoglycosides are problematic because bactericidal activity usually cannot be achieved. As a result, endocarditis caused by these strains can relapse even after prolonged therapy. High-dose or continuous-infusion penicillin has been proposed for treatment of these infections in adults.

Linezolid or daptomycin can be used for VRE infection.

Tigecycline has reliable activity against vancomycin-susceptible and vancomycin-resistant enterococci, but it has not been studied in detail for treatment.[20] Generally, in patients with a catheter-associated enterococcal BSI, the catheter should be removed promptly. In one study of neonates, BSI persisted in all patients until the catheter was removed. In patients with endocarditis caused by aminoglycoside-resistant strains, valve replacement may be necessary.

Prevention

Strategies for preventing enterococcal infection include early removal of urinary and intravenous catheters and debridement of necrotic tissue. Contact isolation is suggested for hospitalized patients known to be colonized or infected with organisms highly resistant to aminoglycosides and vancomycin. A number of trials have addressed the use of unabsorbable antibiotics in attempts to eradicate intestinal colonization with VRE; however, decolonization has not gained wide acceptance. The Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control and Prevention, and the Society for Healthcare Epidemiology of America, have published recommendations for education, an infection control policy, and curtailment of the use of vancomycin to prevent the spread of VRE.[21]

Viridans Streptococci, *Abiotrophia* and *Granulicatella* Species, and *Streptococcus bovis* Group

David B. Haslam, Joseph W. St. Geme III

The viridans streptococci are genetically diverse organisms that share the propensity to colonize humans and occasionally to penetrate local barriers to cause life-threatening disease. Their importance as the predominant cause of endocarditis in children and adults has been known for years. Improvements in identification and classification led to the recognition that these organisms are a significant cause of other infections, including septicemia and meningitis. In this chapter *Abiotrophia* and

Granulicatella (formerly nutritionally variant streptococci [NVS]) and *Streptococcus bovis* group organisms are considered together with viridans streptococci. *S. bovis* is not uniformly classified within the viridans streptococci but shows significant clinical similarities to this group of organisms.

Description of the Pathogen

As is the case with all streptococci, viridans streptococci are gram positive and do not produce catalase. Most are facultatively anaerobes; however, some (including the *S. anginosus* group) are capnophilic, and others are microaerophilic. Viridans streptococci derive their name from the Latin word *viridis,* meaning green, because most isolates cause α-hemolysis on sheep blood agar, producing a ring of greenish discoloration surrounding the colonies. This pattern of hemolysis is predominantly the result of red blood cell damage mediated by hydrogen peroxide, which is released from the organism when it is grown in the presence of oxygen. Notably, many viridans organisms are nonhemolytic when grown in oxygen, and most are nonhemolytic when grown under anaerobic conditions. Although nucleotide sequence homology places *S. pneumoniae* among the viridans streptococci, this species generally is considered separately because of its unique virulence potential. *S. pneumoniae* is differentiated from other viridans streptococci by its optochin susceptibility and bile solubility. Most viridans streptococci fail to react with the Lancefield antisera, but a number of exceptions exist. For example, the *S. anginosus* group contains minute. colony-forming, β-hemolytic organisms that may react with the antisera of Lancefield groups A, C, F, and G.

Speciation

Speciation of the viridans streptococci has been the subject of considerable confusion. Nucleotide sequencing of the 16S ribosomal RNA (rRNA) genes and whole genome sequencing has helped considerably in the classification of these organisms. The viridans streptococci are now classified into five groups, distinguished from *S. bovis* and the pyogenic streptococci (see Fig. 117.1). In the clinical laboratory, viridans streptococcal species are differentiated on the basis of biochemical reactions and patterns of hemolysis (Table 121.1). (The term viridans streptococci is preferred to *Streptococcus viridans* because it avoids the misconception that these organisms belong to a single species or taxon.)

TABLE 121.1

Biochemical Characteristics That Differentiate Viridans Streptococci and *Streptococcus bovis* Group

Organism	Hemolysis	Voges-Proskauer Test	Hydrolysis Of			Acid Production From			
			Esculin	Arginine	H_2O_2	Mannitol	Sorbitol	Lactose	Tre
S. mutans	α, β, γ	+	+	–	–	+	+	+	+
S. mitis	α	–	–	–	+	–	–	+	v
S. oralis	α	–	–	–	+	–	–	+	v

S. intermedius	α, γ	+	+	+	v	v/–	–	+	+
S. bovis group	γ	NA	+	–	NA	+	–	+	+
Gemella morbillorum	α, γ	NA	–	–	NA	–	–	–	–

+, 85% of strains or more test positive; –, 85% of strains or more test negative; NA, not available; v, variable; v/–, variable, usually negative.

Adapted from Sinner SW, Tunkel AR. Viridans streptococci and groups C and G streptococci. In: Mandell GL, Bennett JE, Dolin R (eds). Principles and Practice of Infectious Diseases, 7th ed. New York, Churchill Livingstone, 2009, pp. 2349–2361.

Nonviridans streptococci originally were believed to be mutant forms of *S. mitis*. Biochemical testing and genetic sequence analysis dispelled this notion, and these organisms are now classified as either *Abiotrophia* or *Granulicatella* species. They are fastidious organisms that require pyridoxine (vitamin B_6) or thiol supplementation for growth. Because these requirements can be fulfilled by the metabolic byproducts of other bacteria, nonviridans streptococci grow in culture as satellite colonies around other bacterial species, including *Staphylococcus aureus*.

The automated biochemical identification systems commonly used in clinical microbiology laboratories can lead to incorrect species assignment of viridans streptococcal isolates. Advanced techniques, such as 16S rRNA sequencing or matrix-assisted laser desorption ionization time of flight (MALDI-TOF), generally are more accurate but still have difficulty distinguishing *S. pneumoniae* from *S. mitis* and *S. oralis*.[1]

Nonenterococcal group D organisms comprise the *S. bovis* group, and they are an uncommon cause of disease in children. This group previously was classified into two biotypes, I and II, which were subdivided into subtypes II/1 and II/2. The current classification defines distinct species and subspecies: *S. gallolyticus* (also known as *S. gallolyticus* subsp. *gallolyticus* [formerly *S. bovis* biotype I]); *S. pasteurianus* (also known as *S. gallolyticus* subsp. *pasteurianus* [formerly S. bovis biotype II/2]); *S. lutetiensis* (also known as *S. infantarius* subsp. *coli*); and *S. infantarius* (also known as *S. infantarius* subsp. *infantarius*]). The species *S. lutetiensis* and *S. infantarius* formerly were classified as *S. bovis* biotype II/1.

Among the *S. bovis* group, *S. gallolyticus* accounts for the majority of invasive infections in children and *S. pasteurianus* accounts for most of the remainder. Clinical microbiology laboratories might not be capable of identifying these organisms to the species or subspecies level, an undertaking that can require sequencing of the 16S rRNA gene. In addition, in some parts of the literature these organisms still are referred to simply as *S. bovis*, leading to inconsistency and further confusion.

Virulence Properties

Viridans streptococci lack the classic virulence factors that other streptococci have, such as streptolysin O, streptolysin S, deoxyribonuclease B (DNAase B), adhesion-promoting M and F proteins, and pyrogenic exotoxins. The absence of such factors likely accounts for the low pathogenic potential of these organisms in healthy people. However, some viridans species have a notable predilection for causing endocarditis, a characteristic that appears to correlate with the production of extracellular dextran. *S. mutans, S. sanguis, S. mitis,* and to some extent *S. bovis* most often are implicated in endocarditis, and all produce dextran. Dextran exopolysaccharide might play a dual role in the pathogenesis of endocarditis: mediating bacterial adherence to heart valves, and also rendering organisms relatively resistant to penicillin. *S. mutans* plays an important role in dental caries, one that relates at least in part to adherence to dental enamel, which is mediated by glucan exopolysaccharides. *S. anginosus* has an enhanced propensity to cause localized infections, such as dental and intra-abdominal abscesses. In contrast to other viridans streptococci, *S. anginosus* produces hydrolytic enzymes (e.g., hyaluronidase, DNAase, and chondroitin sulfatase) and can produce neuramidase. The role of these enzymes in pathogenesis remains unclear. Many viridans organisms produce an immunoglobulin (Ig) A protease that presumably attenuates the local immune response and enables the organisms to persist in the mouth.

Epidemiology

Viridans streptococci are ubiquitous inhabitants of the mouth in both children and adults. Oral colonization occurs immediately after birth, and viridans streptococci account for more than 30% of oral bacterial isolates by 8 hours of age. Oral viridans streptococci may confer protection in young infants by preventing the overgrowth of more virulent organisms. Other sites of colonization are the upper respiratory, gastrointestinal, and female reproductive tracts.[2]

The niches that oral streptococci occupy are very well defined. For example, *S. mitis* is predominantly localized to the buccal mucosa, whereas *S. mutans* and *S. sanguis* are associated with the teeth, and *S. salivarius* is localized on the tongue. *S. bovis* is an inhabitant of the lower gastrointestinal tract.

Clinical Manifestations

Endocarditis

Viridans streptococci are the most common cause of bacterial endocarditis in children and adults.[3] In contrast, *S. bovis* rarely is isolated from children with endocarditis. Viridans streptococcal endocarditis is insidious in onset, and diagnosis usually is delayed for several weeks. Fever is almost universally present. Malaise, anorexia, and weight loss can be prominent. Other classic signs of bacterial endocarditis, including splenomegaly, altered cardiac examination findings, petechiae, Osler nodes, Roth spots, Janeway lesions, and splinter hemorrhages, are found with varying frequency.

Major factors in the pathogenesis of bacterial endocarditis are turbulent flow within the heart and bacteremia. Most children with viridans streptococcal endocarditis have either a ventricular septal defect or an abnormal heart valve (because of a congenital defect or rheumatic heart disease). Transient bacteremia is common, particularly after dental trauma, which is an important risk factor for endocarditis. Up to 85% of children undergoing dental extraction have bacteremia, and viridans streptococci are the most commonly isolated organisms.[4]

Abiotrophia and *Granulicatella* species (formerly nonviridans streptococci) account for approximately 5% of cases of endocarditis in adults. Although the frequency of endocarditis caused by these organisms appears to be lower in children, several pediatric cases have been described.[5] Historically these fastidious organisms accounted for occasional cases of “culture-negative endocarditis”; however, most of the blood culture media currently available include L-cysteine or vitamin B_6 and therefore support the growth of these fastidious organisms.

Bacteremia and Septicemia

The significance of recovery of viridans streptococci from blood cultures often is difficult to determine. Isolation is more significant if growth is pure and is found in more than one blood culture bottle or set.

Viridans streptococci are a common cause of septicemia in children with cancer[6]; a particularly strong association has been noted between high-dose cytarabine treatment and viridans streptococcal bloodstream infection (BSI). Mucositis and prolonged granulocytopenia are associated risk factors. Viridans streptococci typically are resistant to trimethoprim-sulfamethoxazole (TMP-SMX), and invasion of these organisms may be enhanced by TMP-SMX prophylaxis.[7]

Patients with viridans streptococcal BSI are prone to pulmonary complications, including respiratory distress syndrome, and meningitis. Patients with respiratory distress syndrome can develop septic shock and deteriorate rapidly despite appropriate antimicrobial therapy. These fulminant cases generally are caused by *S. mitis,* tend to occur after bone marrow transplantation, and are more common in children than adults.[8] Notably, a high proportion of causative organisms are resistant to penicillin and cephalosporins; vancomycin usually is added to empiric treatment of neutropenic patients in whom viridans streptococcal infection is suspected.[9]

Approximately 3% to 5% of neonatal BSIs are caused by viridans streptococci.[10] The risk factors, which are similar to those for BSI caused by other organisms, include prematurity, low birth weight, and prolonged rupture of amniotic membranes. The clinical presentation of viridans streptococcal infection resembles that of early onset infection caused by group B streptococci, and the predominant feature is respiratory distress. However, with viridans-type infections, the onset tends to occur later (mean age 3.5 days, compared with <12 hours for group B–type infections), and the incidence is lower for leukopenia, an abnormal immature to total neutrophil ratio, and thrombocytopenia. Associated localized infections are uncommon, although a case report has described an infant with septicemia and meningitis associated with a scalp abscess caused by viridans streptococci.[11]

Among children without an underlying condition, isolation of viridans streptococci from blood cultures generally does not correlate with any disease state. In most cases the patient remains asymptomatic even without specific therapy.[12,13]

Organisms of the *S. bovis* group occasionally are reported as a cause of neonatal BSI, often in association with a primary intestinal disorder.[14] The true incidence of septicemia caused by *S. bovis* group organisms is difficult to determine because some studies might classify the organisms among the enterococci (as a group D *Streptococcus*), and others might assign them to the viridans streptococci. No clinical features distinguish neonatal BSI caused by organisms of the *S. bovis* group from that caused by more typical neonatal pathogens. In rare cases, BSI caused by organisms of the *S. bovis* group is complicated by meningitis, especially when *S. pasteurianus* is the causative organism.[15]

Other Infections

Viridans streptococci can cause pyogenic infections, including brain abscess and localized intra-abdominal infections, such as hepatic and subphrenic abscesses. Organisms of the *S. anginosus* group account for most such infections, reflecting their proclivity for causing localized pyogenic infections, frequently in association with other organisms (Fig. 121.1).

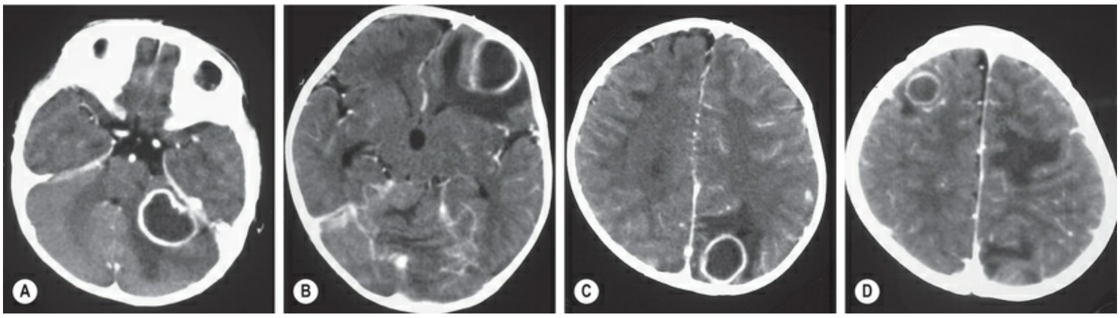

FIGURE 121.1 Multiple brain abscesses caused by *Streptococcus intermedius* and *Eikenella corrodens* in an 11-month-old girl with tricuspid atresia and pulmonary-to-systemic shunting of blood after a hemi-Fontan procedure. She had a 5-day history of fever, irritability, and shaking chills and then a right-sided seizure. She did not have a respiratory illness, exposure to pets, pneumonia, or endocarditis. Axial contrast-enhanced CT shows ring-enhancing brain abscesses with surrounding edema in the left cerebellar hemisphere (A), the frontal (B) and parietal (C) lobes, and the right parietal lobe (D), indicating multifocal vascular territories. Note the additional areas of cerebral edema in contralateral hemispheres (D) related to other abscesses. (Courtesy of E.N. Faerber and S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Viridans streptococci are a rare cause of meningitis, accounting for approximately 0.3% to 3% of cases in adults. Few data exist for children, although one study implicated viridans streptococci in approximately 1% of pediatric cases.[16] Most children are younger than 1 year of age and have concomitant BSI. Predisposing factors in older children include endocarditis and trauma or surgery involving the central nervous system.

Dental infections, including dental caries, abscesses, and periodontal disease, often are caused by viridans streptococci, most commonly *S. mutans* and *S. anginosus*. These infections usually are polymicrobial, but viridans streptococci sometimes are isolated as sole pathogens.

Pneumonia, empyema, sinusitis, and otitis media occasionally are ascribed to viridans streptococci. However, because these organisms colonize the mouth in such high numbers, ascribing to them a causative role in respiratory tract infection is difficult except when they are isolated from culture of percutaneously aspirated specimens. Pure growth of a viridans streptococcus has been obtained from bronchoscopy material and from aspirated pleural fluid.[17] In addition, growing evidence indicates a role for *S. anginosus* as a contributor to pulmonary disease in some patients with cystic fibrosis.

Treatment

Historically, more than 80% of viridans streptococci were susceptible to penicillin (minimum inhibitory concentration [MIC] ≤0.1 μg/mL). However, resistance is increasing, perhaps as a consequence of the widespread use of β-lactam antibiotics.[18] Strains with an MIC greater than 0.12 μg/mL and less than 0.5 μg/mL are classified by the American Heart Association (AHA) as relatively resistant; those with an MIC of 0.5 μg/mL or greater are considered resistant. Tolerance (a ratio of minimum bactericidal concentration to MIC greater than 32) is uncommon among viridans streptococci, and its clinical significance is unclear. High penicillin resistance (MIC >4 μg/mL) has been described but remains rare in North America. Viridans streptococci that are resistant to β-lactams appear to have altered penicillin-binding proteins (PBPs). The nucleotide sequence of the *PBP 2B* gene from highly resistant *S. pneumoniae* demonstrates a striking homology with the *PBP 2B* gene from resistant *S. oralis* isolates, which suggests transfer of the mutated gene between the two species.[19]

Viridans streptococci are resistant to aminoglycosides used as single agents. However, aminoglycosides are synergistically bactericidal when combined with β-lactam agents. Cephalosporins (especially ceftriaxone), vancomycin, teicoplanin, meropenem, and chloramphenicol generally have good activity against viridans streptococci. Susceptibility to tetracycline, clindamycin, and erythromycin is variable, and most isolates are resistant to TMP-SMX. Linezolid, tigecycline, and daptomycin are active against the viridans streptococci resistant to β-lactams, but clinical experience in the treatment of viridans-type infections with these drugs is limited.

Approximately one half of the *Abiotrophia* and *Granulicatella* species are at least relatively resistant to penicillin, and occasional isolates demonstrate high resistance.[20] Furthermore, strains that apparently are susceptible to penicillin often are tolerant to bactericidal activity. Relative resistance to aminoglycosides also is common, although high resistance (MIC >500 μg/mL) has not been described. Combination therapy with a cell wall–active agent (e.g., penicillin or vancomycin) and an aminoglycoside results in synergistic bactericidal activity.

The AHA's therapeutic recommendations for viridans streptococcal endocarditis involving native valves can be found in Tables 37.6 and 37.7. Endocarditis caused by isolates susceptible to penicillin (MIC ≤0.12 μg/mL) can be treated with penicillin alone for 4 weeks. As an alternative, the combination of penicillin plus an aminoglycoside can be used for 2 weeks, with or without 2 additional weeks of penicillin alone. Relatively resistant isolates (MIC >0.12 to <0.5 μg/mL) are treated with penicillin plus an aminoglycoside for 2 weeks, followed by 2 weeks of penicillin alone. Patients with penicillin-resistant isolates (MIC >0.5 μg/mL) are treated for 4 to 6 weeks with both penicillin and an aminoglycoside. Vancomycin can be substituted for penicillin in patients who have immediate-type hypersensitivity to penicillin. A 4-week course of vancomycin is recommended if the isolate has a penicillin MIC less than 0.5 μg/mL. If the isolate's MIC is 0.5 μg/mL or greater, the patient should be treated with 4 to 6 weeks of vancomycin plus an aminoglycoside. For the treatment of endocarditis involving prosthetic valves or caused by organisms other than viridans streptococci, the reader is referred to Chapter 37 and the AHA's recommendations.[21]

Some cases of endocarditis in children do not respond to antimicrobial treatment alone and require operative therapy. Relative indications for surgical intervention include persistent infection, embolic phenomena, and worsening of congestive heart failure.

Septicemia, meningitis, and other serious infections caused by viridans streptococci that are fully susceptible to penicillin can be treated with penicillin alone or in combination with an aminoglycoside. Vancomycin is the drug of choice in patients allergic to penicillin or when organisms highly resistant to penicillin have been isolated. Empiric therapy for viridans streptococcal sepsis in children with cancer should include vancomycin, linezolid, or daptomycin because resistance to these agents remains rare among organisms of the *S. mitis* group. If the isolate testing results are favorable, treatment with a β-lactam is superior.

Penicillin is the treatment of choice for infections caused by organisms of the *S. bovis* group because virtually all these isolates are susceptible (MIC <0.1 μg/mL). A single isolate of the *S. bovis* group that demonstrates the *vanB v*ancomycin resistance gene has been described.[22]

Prevention

Measures to prevent viridans streptococcal septicemia in children with cancer include assiduous mouth care and maintenance of oral hygiene, particularly when mucositis is present. Studies suggest that penicillin prophylaxis for neutropenic patients may reduce the incidence of viridans streptococcal septicemia; however, this practice can lead to a greater prevalence of penicillin-resistant organisms and is not currently widespread.

Prevention of endocarditis requires identification of children at risk and stratification of the risk by a cardiologist. The AHA recommends prophylaxis for patients with prosthetic cardiac valves, those who previously have had infectious endocarditis; recipients of a cardiac transplant with cardiac valvulopathy; and certain patients with congenital heart disease.[23] Candidates for prophylaxis are given an antimicrobial agent for tonsillectomy, adenoidectomy, and dental procedures involving manipulation of the gingival tissue or the periapical region of the teeth, or perforation of the oral mucosa.

Ampicillin remains the mainstay of prophylactic therapy. Different recommendations have been established for patients who are allergic to penicillin, unable to take oral medications, or receiving chronic antibiotic prophylaxis, and also for those undergoing procedures such as drainage of focal respiratory infection or manipulation of infected skin or musculoskeletal tissue. The reader is referred to the AHA recommendations[23] and Chapter 7.

Groups C and G Streptococci

David B. Haslam, Joseph W. St. Geme III

The β-hemolytic streptococci can be subdivided on the basis of whether they form large colonies or minute colonies on solid agar. Most notable among those β-hemolytic streptococci that form large colonies are *Streptococcus pyogenes* (group A) and *Streptococcus agalactiae* (group B). Among the remaining Lancefield-reactive β-hemolytic streptococci, groups C and G organisms are most commonly associated with human disease.[1] In this chapter, groups C and G streptococci refer exclusively to the large-colony–forming "*S. pyogenes*-like" organisms. Minute-colony–forming species belonging to groups C and G are placed in the *S. anginosus* group (formerly *Streptococcus milleri)* (see Chapter 121). In some hospitals, group G streptococci cause more cases of invasive disease than does *S. pyogenes*,[1] perhaps because these organisms are more commonly associated with infection in immunocompromised hosts.

Characteristics of the Pathogens

Groups C and G organisms, like all streptococci, are catalase-negative, gram-positive cocci. Human isolates are almost always β hemolytic on sheep blood agar culture, although rare isolates are α hemolytic or nonhemolytic. Groups C and G organisms resemble *S. pyogenes* on blood agar, thus necessitating biochemical testing and serologic analysis for definitive identification. Latex agglutination typically is used in clinical microbiology laboratories to determine the Lancefield grouping of large-colony β-hemolytic streptococci. Most groups C and G isolates are resistant to bacitracin, but significant fractions are susceptible, thereby making bacitracin susceptibility testing alone unreliable in distinguishing these organisms from *S. pyogenes.* Hydrolysis of L-pyrrolidonyl-P-naphthylamide (PYR reaction) is a useful adjunctive test because the groups C and G organisms are PYR negative and *S. pyogenes* is PYR positive. Colony morphology and lack of acetoin production (negative results of the Voges-Proskauer [VP] test) differentiate large-colony groups C and G streptococci from the *S. anginosus* group (Table 122.1).

TABLE 122.1

Differentiation of β-Hemolytic Group C and G Isolates From *Streptococcus pyogenes* and *Streptococcus anginosus*

Organism	**Lancefield Group**	**Bacitracin**	**PYR Test Result**	**VP Test Result**
Streptococcus pyogenes–like groups C and G, large-colony–forming (*Streptococcus dysgalactiae* subspecies *equisimilis*)	C or G	Resistant[a]	−	−
S. pyogenes	A	Sensitive	+	−
Minute-colony–forming groups C and G (*Streptococcus anginosus* group)	C or G	NA	NA	+

[a] Occasional isolates are susceptible to bacitracin.

+, most isolates produce a positive reaction; −, most isolates produce a negative reaction; NA, data not available; PYR, L-pyrrolidonyl-β-naphthylamide; VP, Voges-Proskauer.

Speciation

Large-colony Group C and G human isolates now are grouped together as *Streptococcus dysgalactiae* subsp. *equisimilis*.[2] The remaining large-colony group C streptococci, predominantly animal pathogens, are grouped as *S. dysgalactiae* subsp. *dysgalactiae*. Nonhuman group G isolates are often considered part of a single species designated as *Streptococcus canis* and are genetically distinct from the *S. dysgalactiae* subsp. *equisimilis* group G organisms.

Virulence Properties

Groups C and G streptococci share several virulence factors with *S. pyogenes*. Both group C and group G isolates produce streptolysin O and can stimulate an increase in the anti–streptolysin O (ASO) titer. In addition, isolates of both groups produce degradative enzymes, including hyaluronidase.

Group G isolates also produce streptolysin S and often produce DNAase that is antigenically similar to *S. pyogenes* DNAase B. Moreover, group G streptococci produce an M protein that is similar immunologically to that of *S. pyogenes* and can be responsible for the occasional association of group G isolates with postinfectious glomerulonephritis. Glomerulonephritis following group C streptococcal infection also is well described. Whereas these isolates fail to produce an M protein, they can produce endostreptosin, which is believed to be involved in the pathogenesis of *S. pyogenes*–induced glomerulonephritis.

A toxic shock–like syndrome associated with group C and G streptococcal infection has been reported. Some of these cases have been associated with a strain that possesses genes homologous to the *S. pyogenes* streptococcal pyogenic exotoxins or that elaborates an unidentified substance with superantigen activity.[3]

Epidemiology

Pharyngeal carriage of groups C and G streptococci is detected in up to 5% of healthy children. In tropical climates, the pharyngeal carriage rate is much higher. The skin, gastrointestinal tract, and vagina also are frequent sites of colonization with groups C and G streptococci. *S. dysgalactiae* subsp. *equisimilis* can be isolated from the umbilicus of healthy neonates but rarely causes invasive disease.

Clinical Manifestations

Groups C and G streptococci are associated with the same spectrum of illnesses caused by *S. pyogenes*. In children, these organisms are implicated most commonly in respiratory tract infections, particularly pharyngitis. The true incidence of pharyngitis caused by groups C and G streptococci is difficult to determine because asymptomatic colonization occurs.[4] Nevertheless, compelling evidence implicates group C and G streptococci as true causes of pharyngitis. For example, several epidemics of group C and group G streptococcal pharyngitis have been reported. Even more convincing support comes from studies of foodborne outbreaks. The clinical presentation of pharyngitis resulting from groups C and G streptococci is indistinguishable from pharyngitis caused by *S. pyogenes*.[5]

Isolated case reports have described group C streptococcal pneumonia in children. Similar to group A streptococcal infection, tissue destruction is considerable. Abscess formation, empyema, and bacteremia are common. Despite effective antimicrobial therapy, these infections typically respond slowly, with persistent fever for >7 days.[6] Other respiratory tract infections reported include epiglottitis[7] and sinusitis.

Groups C and G streptococci also cause skin and soft tissue infections. These organisms can colonize the skin and gain access to subcutaneous tissues after a break in skin integrity. As with *S. pyogenes* infection, lymphangitis can complicate superficial infections caused by groups C and G organisms. Musculoskeletal infections, particularly pyogenic arthritis, occur occasionally, usually in adults with underlying disease.[8] At least 3 well-documented pediatric cases resulting from group C streptococci have been described.[9]

Groups C and G streptococci can cause neonatal septicemia and account for up to 2% of cases in some series. Risk factors include prematurity, prolonged rupture of membranes, and maternal infection. The clinical course may be indistinguishable from early-onset group B *Streptococcus* infection and includes respiratory distress, hypotension, apnea, bradycardia, and disseminated intravascular coagulation. Neonatal streptococcal toxic shock syndrome caused by *S. dysgalactiae* subsp. *equisimilis* has been described.[10]

Endocarditis, bacteremia, central nervous system infections (particularly brain abscess), and toxic shock caused by groups C and G streptococci are described but are uncommon in children. These infections generally occur in children with immune deficits or in adolescents after delayed recognition of sinusitis.

In addition to the postinfectious glomerulonephritis associated with infection with groups C and G streptococci, reactive arthritis has been described after group C streptococcal infection. No convincing evidence of acute rheumatic fever after infection with groups C and G streptococci has been found; therefore, antibiotic treatment is not indicated to prevent rheumatic fever.[11]

Therapy

Groups C and G streptococci are inhibited by low concentrations of penicillin (mean minimum inhibitory concentration <0.2 μg/mL), and penicillin is the drug of choice in most circumstances.[12] However, some isolates demonstrate tolerance to penicillin, with a ratio of minimal bactericidal concentration to minimum inhibitory concentration as high as 512 : 1. Although the clinical significance of tolerance is unclear, one study demonstrated that in adults with endocarditis resulting from tolerant group C streptococci infection, treatment with penicillin and an aminoglycoside resulted in improved outcome.

Other antibiotics with activity against groups C and G streptococci include other β-lactam agents, carbapenems, linezolid, quinupristin-dalfopristin, and vancomycin.[13] Occasional isolates demonstrate tolerance to vancomycin. Chloramphenicol, clindamycin, and erythromycin have poor bactericidal activity, particularly against group G streptococci. Up to 70% of group C streptococci produce a chromosomally encoded factor that mediates resistance to tetracycline.

Streptococcus pneumoniae

Krow Ampofo, Carrie L. Byington

In the introduction to his classic 1938 monograph *The Biology of the Pneumococcus,* Benjamin White wrote that the "pneumococcus is altogether an amazing cell. Tiny in size, simple in structure, frail in make-up, it possesses physiological functions of great variety, performs biochemical feats of extraordinary intricacy and, attacking man, sets up a stormy disease so often fatal that it must be reckoned as one of the foremost causes of human death."[1] Currently the pneumococcus remains a major cause of respiratory and invasive diseases and contributes significantly to mortality rates in children younger than 5 years of age.[2,3]

Characteristics of the Pathogen

Microbiology

Streptococcus pneumoniae is a gram-positive, catalase-negative, facultatively anaerobic organism that grows as lancet-shaped diplococci and in short chains. Growth is enhanced in 5% carbon dioxide or anaerobic conditions. Autolysis can be responsible for failure of the organism to grow in subculture despite a positive Gram stain reaction. On blood agar, colonies are α hemolytic and can be identified presumptively from their susceptibility to optochin or the latex agglutination test. The specific pneumococcal type based on polysaccharide capsule can be identified using pooled typing sera and microscopic examination or by molecular techniques.

More than 90 immunologically distinct capsular polysaccharide serotypes within 45 serogroups have been identified.[4] In the widely accepted Danish system, serotypes are grouped according to antigenic similarities. For example, serogroup 9 includes types 9A, 9L, 9N, and 9V. Immunologic cross-reactivity among serotypes in the same serogroup can result in some cross-protection, but no cross-reactivity exists among different serogroups.[5]

Nucleic acid amplification tests such as real-time polymerase chain reaction (PCR) have been used for *S. pneumoniae* identification and have improved pneumococcal diagnosis. These assays rely on amplification of several gene sequences such as autolysin (*lytA*), pneumolysin (*ply*), and pneumococcal surface adhesion (*psa A*) to identify *S. pneumoniae*.[6–8] Although they are useful in the rapid identification of *S. pneumoniae* in cultured colonies,[6] these assays also have been used to detect and serotype *S. pneumoniae* in a variety of clinical specimens including blood, middle ear fluid,[6] tissue,[9] cerebrospinal fluid (CSF),[10] and pleural fluid.[11–13] PCR-based techniques interrogate the *S. pneumoniae* gene responsible for capsular polysaccharide synthesis located at the *cps* locus. Serotype is determined by amplification of the entire *cps* locus, followed by restricted fragment length polymorphism analysis[14] or by a sequence-based system using multiplex PCR.[15] The advantage of the PCR-based assay is that the test can be applied to cultivated colonies or to tissue or body fluids in the absence of viable isolates.[10,13]

Before 2000 and the licensure of the 7-valent conjugate pneumococcal vaccine (PCV7) in the United States, most pneumococcal disease was caused by relatively few serotypes. The most frequent types responsible for acute otitis media (AOM) in children were 23F, 19F, 6B, 6A, 14, 19A, 11, 15, 18C, 3, and 9V, although the rank varied by geographic location as exemplified by data from Finland,[5] Alabama,[16] and the Czech Republic and Slovakia.[17] Serotypes responsible for invasive pneumococcal disease (IPD) such as bacteremia, septicemia, or meningitis also were limited, with infection by types 14, 6B, 19F, 18C, 23F, 4, and 9V most common. [18] Shifts in AOM and IPD serotype distribution occurred following PCV7 implementation. Emerging AOM types included the non-PCV7 serotypes 3, 6A, 6C, and 19A.[19–22] By the late PCV7 era (2008–2010), *S. pneumoniae* was isolated from 26% to 36% of 227 children with AOM who underwent tympanocentesis in Rochester, New York. No PCV7 serotypes were found, whereas serotypes 19A and 15 were detected most frequently.[23] Similarly, serotypes responsible for IPD reflected increases in non-PCV7 types including 3, 15, 19A, 22F, and 33F, with serotype 19A the predominant cause of culture-confirmed IPD in US children.[24–27] By 2007, up to 61% of IPD cases in children <5 years of age were caused by non-PCV7 serotypes.[28,29] Strain replacement (in part facilitated by capsular switching[30–32]) in response to the selective pressure exerted by a successful pneumococcal vaccine program that targeted a limited number of serotypes was feared to limit the utility of PCVs. In response, a 13-valent vaccine (13-valent pneumococcal conjugate vaccine [PCV13]) was licensed to replace the use of PCV7 in children in 2010.[33] PCV13 contains the 7 serotypes in PCV7 (4, 6B, 9V, 14, 18C, 19F, and 23F) and 6 additional serotypes (1, 3, 5, 6A, 7F, and 19A). Similarly, with the widespread use of PCV13, IPD caused by PCV7 serotypes as well as the additional 6 serotypes in PCV13 has declined substantially.[34]

Pathogenesis and Virulence

The most important factors in the development of pneumococcal disease are the virulence of the serotype, the absence of type-specific humoral immunity, and the presence of viral respiratory tract disease. *S. pneumoniae* colonizes the nasopharynx of healthy children and can infect the middle ear, sinuses, and lungs by contiguous spread or can invade the bloodstream and establish foci in the meninges and other sites. Pneumococcal AOM is associated with recent nasopharyngeal acquisition of a serotype, rather than the result of prolonged colonization (carriage).[35,36] Recent acquisition also is associated with IPD. Not all pneumococcal types are equally invasive. The composition and quantity of capsular polysaccharide have major roles in virulence and invasive potential. Thus, although certain serotypes are infrequently isolated from the nasopharynx, they can contribute disproportionately to IPD. In large studies from Finland, the United Kingdom, Chile, Israel, Taiwan, and the Czech Republic, serotypes 1, 4, 5, 6B, 9V, 14, 18C, 19A, and 19F were overrepresented in IPD compared with nasopharyngeal colonization in children <5 years of age.[37–42] Similarly, serotypes 1, 3, 5, 18C, 19A, and 19F were overrepresented among AOM isolates compared with nasopharyngeal isolates in children <5 years of age.[43]

Once the pneumococcus enters the bloodstream, encapsulation provides protection from host defense mechanisms by inhibiting neutrophil phagocytosis and classic complement-mediated bactericidal activity. Several protein virulence factors, such as *ply* and *psa A*, have been identified from studies in experimental animals.[44]

In the healthy host, bacteria reaching the lung usually are cleared rapidly by alveolar macrophages or migrating neutrophils. Pneumonia results when disruption of the integrity of the epithelium of the lower respiratory tract is caused by microbiologic (e.g., viral infection), chemical (e.g., alcohol), or mechanical (e.g., aspiration) factors. Bacterial clearance is delayed, resulting in proliferation of *S. pneumoniae*. The role of respiratory viral infection as an antecedent or copathogen with *S. pneumoniae* is suggested by the seasonality of IPD that correlates with respiratory virus activity.[45–47] Further, in pneumococcal vaccine trials, the 9-valent vaccine prevented 31% of cases of pneumonia associated with respiratory viruses in children.[48,49]

Immunity

The polysaccharide capsules of pneumococci are chemically distinct and have immunologically specific features that form the basis of vaccine development. Type-specific protective antibodies against capsular polysaccharide develop after pneumococcal disease or immunization. Children <2 years old require immunization with protein conjugate vaccine to produce type-specific antibody. Antibody facilitates destruction of the pneumococcus by complement-mediated lysis and protects against both local and invasive disease.

Carriage of a particular serotype usually does not produce immunity sufficient to prevent reacquisition of that serotype. Human breast milk can protect infants from pneumococcal infection,[50,51] but specific protective factors have not been identified.

Epidemiology

Initial acquisition of pneumococci occurs in the first months of life, with a mean age of 6 months.[52] In developing countries, cumulative acquisition in several studies has exceeded 90% before 6 months of age. Nasopharyngeal carriage rates have been reported to range from 11% to 93% and vary by age, geographic region, and population.[52–55] In a study of healthy families in Charlottesville, Virginia, carriage rates were as high as 35% in preschool-aged and school-aged children, with lower rates in adolescents (9%). Adults with preschool-aged children have higher rates of carriage (18%) than do adults without children in this age group (9%).[56] Duration of carriage varies with serotype, is inversely correlated with age, and most commonly is 2 to 4 months, but it can be longer.[35,57,58]

Nasopharyngeal carriage of PCV7, PCV10, and PCV13 serotypes decreases in children who have received vaccine, but carriage of nonvaccine serotypes increases.[59,60] In clinical trials comparing PCV13 with PCV7, additional declines in nasopharyngeal carriage of serotypes 1, 6A, 6C, 7F, 19A, and 19F were observed in PCV13 recipients when compared with PCV7 recipients.[61] Factors associated with higher carriage rates include age <2 years, attendance at out-of-home childcare, crowding, winter, and parental smoking.[52,62]

Pneumococci are transmitted from person to person by respiratory droplets. Most disease is episodic, but epidemic disease has occurred in closed populations, such as military recruits,[63] and clusters of cases of IPD have been reported in children attending childcare facilities.[64]

Although type-specific immunity results from previous infection, recurrent infections by the same pneumococcal type can occur in immunocompromised hosts. Recurrent episodes of IPD occur in ~2.5% of patients who survive their initial episode.[65,66] The risk of recurrence is higher in persons with human immunodeficiency virus (HIV) infection and children <5 years of age who have chronic illness. Recurrent pneumococcal meningitis is associated with congenital or acquired disruption of the integrity of the skull, such as fractures of the cribriform plate and nasal, otic, or neurosurgical procedures.

The highest age-specific attack rate of IPD occurs in the first 2 years of life, with a peak between 6 and 11 months of age. This pattern continued during the PCV7 era. Following implementation of PCV13, further declines in IPD occurred in all age groups, especially among children <5 years of age (Fig. 123.1).[27,67] Boys are more commonly affected than girls in most studies. Type-specific antibody is passively transferred from the mother to the newborn and protects infants in the first several months. Accordingly, pneumococcal septicemia is rare in newborns; neonates accounted for only 20 cases in a review of 4428 episodes of IPD from 1993 to 2001.[68] In another series, infants 1 to 90 days of age accounted for 36 of 513 (7%) cases of IPD.[69] In neonatal infection the organism usually is acquired from the maternal genital tract, and both early onset and late onset disease has been reported.[68–70]

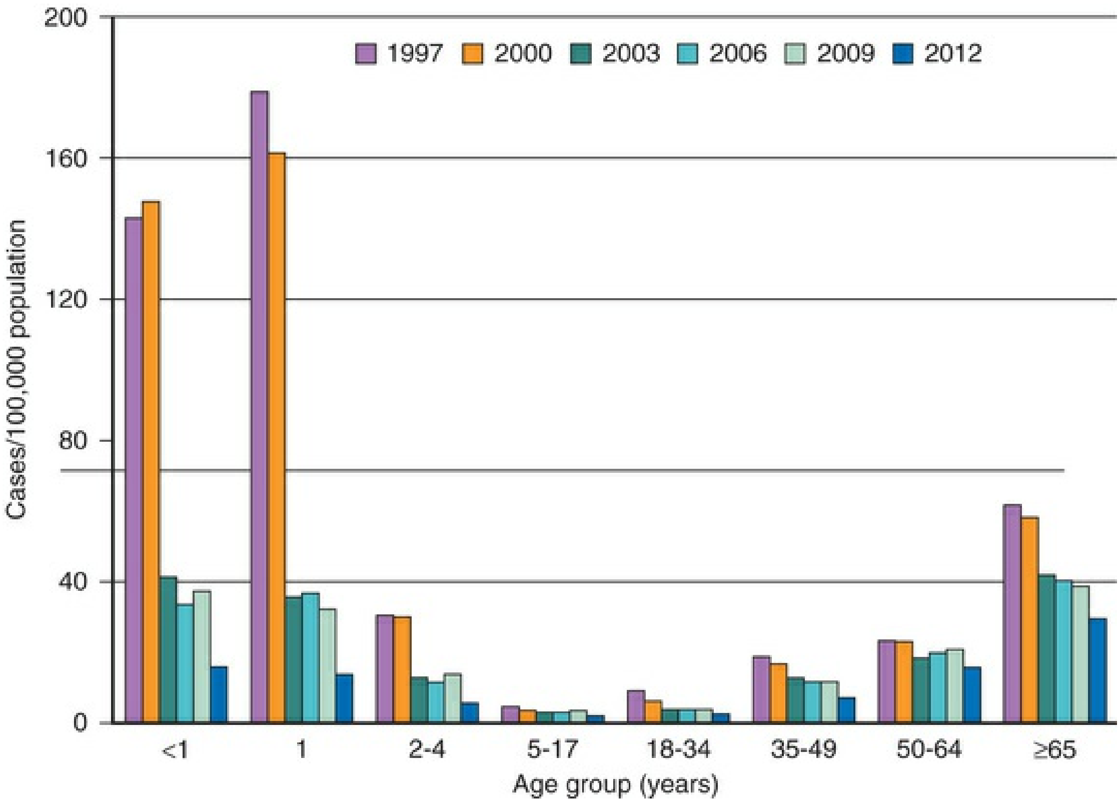

FIGURE 123.1 **Rates of invasive pneumococcal disease by age group in the United States in 1997, 2000, 2003, 2006, 2009, and 2012.** (Redrawn from Centers for Disease Control and Prevention. Active Bacterial Core Surveillance [ABCs]/Emerging Infectious Program [EIP] Network, 2015. www.cdc.gov/abcs/reports-findings/surv-reports.html.)

Children with certain underlying conditions are at high risk of IPD (Table 123.1). In the US before the introduction of PCV7, African Americans, Alaska Natives, and members of specific American Indian groups had higher rates of IPD compared with white people[59,71]; following introduction of PCV7 the racial disparity for IPD compared with whites diminished but has not disappeared.[26,72–75] The extent to which increased risks are attributable to other factors is not clear. The increased risk of race persists despite controlling for income.[59] Some case-control studies have demonstrated the strong association of IPD with underlying disease, larger family size,[51] and attendance at out-of-home childcare in the preceding 3 months.[50] Immunization with PCV7 did not influence the risk for non–vaccine-type IPD.[27] Since the introduction of PCV13, IPD occurs disproportionately in children with high-risk medical conditions that are indications for pneumococcal vaccination.[34,76]

TABLE 123.1

Underlying Medical Conditions That Are Indications for 23-Valent Pneumococcal Polysaccharide Vaccination Among Children ≥2 Years of Age

Risk Group	Condition
Immunocompetent children	Chronic heart disease[a] Chronic lung disease[b] Diabetes mellitus Cerebrospinal fluid leaks Cochlear implant
Children with functional or anatomic asplenia	Sickle cell disease or other hemoglobinopathy Congenital or acquired asplenia or dysfunction
Children with immunocompromising conditions	Human immunodeficiency virus infection Chronic renal failure or nephrotic syndrome Diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemia, and lymphoma, including Hodgkin disease; or solid-organ transplantation Congenital immunodeficiency[c]

[a] Particularly cyanotic congenital heart disease and cardiac failure.

[b] Including asthma if treated with high-dose oral corticosteroid therapy.

[c] Includes B-lymphocyte (humoral) or T-lymphocyte deficiency; complement deficiencies, particularly C1, C2, C3, and C4 deficiency; and phagocytic disorders (excluding chronic granulomatous disease).

From the AAP Committee on Infectious Diseases. Pneumococcal infections. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. Red Book: 2015 Report of the Committee on Infectious Diseases. 30th ed. Elk Groove Village, IL: American Academy of Pediatrics; 2015:626–638.

Children with sickle cell disease (SCD) or with HIV infection, especially those <3 years of age, have a markedly higher incidence of IPD.[59,77] The risk also is increased in children with other hemoglobinopathies, asplenia, nephrotic syndrome, and immunodeficiency other than HIV infection and in children receiving immunosuppressive therapy or who have CSF leaks (see Table 123.1).[33,59,77–79] Children with a cochlear implant, in particular those who received an implant with a positioner, have an increased risk for pneumococcal meningitis.[80]

Clinical Manifestations

The manifestations of pneumococcal infection are not distinct from those caused by other bacteria. The major exception is the classic syndrome of pneumococcal pneumonia described here that occurs in older children and adults.

In the pre-PCV7 era, the most common pneumococcal infections were AOM, pneumonia, and bacteremia with or without a focus, also termed "occult bacteremia."[59] In infants and young children with occult bacteremia, *S. pneumoniae* was the predominant isolate, accounting for 83% and 92% of cases in 2 studies in the post–*Haemophilus influenzae* type b conjugate vaccine and pre-PCV7 era.[81,82] In the PCV era, occult bacteremia in febrile children is uncommon in the United States.[83–89] However, when present, occult pneumococcal bacteremia can be caused by non-PCV7 serotypes.[90–92] Pneumococcal bloodstream infection in patients with SCD or asplenia can have a rapidly progressive course marked by abrupt onset, purpura, disseminated intravascular coagulation, and death within 24 to 48 hours; the course resembles that of Waterhouse-Friderichsen syndrome.

In the US, *S. pneumoniae* remains a leading bacterial cause of community-acquired pneumonia, although ~70% of cases of pneumonia occurring beyond the neonatal period are caused by respiratory viruses.[93] Data from PCV7 trials indicated that *S. pneumoniae* was responsible for approximately one third of radiographically diagnosed cases of pneumonia in infants.[94] However, in the Centers for Disease Control and Prevention (CDC) Etiology of Pneumonia in the Community (EPIC) study of children hospitalized with radiographically confirmed pneumonia in 3 children's hospitals in the US from January 2010 to June 2012, a bacterial pathogen was detected in only 15% of children, with *S. pneumoniae* the second most common bacterial pathogen detected after *Mycoplasma pneumoniae*.[93]

The classic presentation of pneumococcal pneumonia in older children includes a prodrome of viral respiratory tract infection (typically) followed by the abrupt onset of shaking chills, high fever, pleural pain, dyspnea, prostration, rust-colored sputum, and radiographic and physical findings indicating lobar consolidation. The spectrum of manifestations of pneumococcal pneumonia in infants and young children is broad and includes mild, nonspecific respiratory symptoms; cough can be absent, at least initially. In infants and toddlers, fever, vomiting, abdominal distention, and pain can be predominant, even suggesting appendicitis. Patients with right upper lobe pneumonia can have nuchal rigidity suggestive of meningitis.[95]

The characteristic radiographic finding in adolescents and adults is lobar consolidation, but in infants and young children, bronchopneumonia with scattered distribution of alveolar and parenchymal consolidation is common. Other radiographic findings are pleural fluid, lung abscess resulting from necrotizing lobar pneumonia, and, infrequently, pneumatoceles.

Although *S. pneumoniae* continues to be a leading cause of pediatric bacterial pneumonia, the overall rates of pneumonia significantly declined following the introduction of PCV7.[27,94,96–98] Other countries where PCV13 has replaced PCV7 report a further 27% to 64% decline in cases of bacterial pneumonia in hospitalized patients.[34,99–101] In contrast to pneumonia, hospitalizations for complicated pneumonia, effusion, empyema, lung abscess, and necrosis caused by *S. pneumoniae* increased in regions of the world with widespread use of PCV7.[11,102–104] In children with pleural empyema, *S. pneumoniae* continues to be the leading cause in the US and worldwide, although pleural empyema resulting from methicillin-resistant *Staphylococcus aureus* (MRSA) has increased.[13,104,105] An increased incidence of empyema has been associated with *S. pneumoniae* serotypes 1, 3, 7A, and 19A,[13,106–108] and necrotizing pneumonia has been associated with serotype 3.[109] Incidence rates of parapneumonic empyema have decreased by 50% since the introduction of PCV13 in the US.[101]

Among children with pneumococcal meningitis, approximately one half will manifest the classic triad of fever, nuchal rigidity, and change in mental status, and others have at least one of these findings.[110] Common manifestations vary by age in children: seizures, irritability, diarrhea, and a bulging fontanelle at <6 months of age; vomiting, altered mental status, and poor feeding between 6 months and 2 years; neck stiffness, vomiting, and drowsiness between 2 and 10 years; and neck stiffness, focal neurologic sign, headache, and vomiting >10 years of age.[111] CSF often has the following features: typical lancet-shaped, gram-positive cocci in pairs, with accompanying pleocytosis (predominantly neutrophils); a low CSF-to–serum glucose ratio (<0.6); and a high CSF protein concentration. In children with confirmed pneumococcal meningitis, CSF culture results are positive in >90%, and blood culture results are positive in ~75%.[110,112] Common complications associated with pneumococcal meningitis include, shock, respiratory failure, and residual neurologic sequelae, including hearing loss, seizures, and motor and behavioral deficits.[113–117] Neurologic morbidity following pneumococcal meningitis in a contemporary series occurred in 63% of survivors.[117] Features associated with increased morbidity and mortality rates include altered mental status and shock at admission, as well as low CSF white blood cell count and glucose concentration.[110,118]

Pneumococcal diseases also include conjunctivitis,[119–121] sinusitis,[122] soft tissue infections (e.g., buccal and periorbital cellulitis, erysipelas, cystic gingival lesions, and glossitis),[123,124] and invasive infections, including peritonitis,[125] pyogenic arthritis and osteomyelitis,[126] tubo-ovarian abscess and salpingitis,[127] and endocarditis.[128,129] Rare complications of pneumococcal infection include hemorrhage and shock,[130] hemolytic uremic syndrome,[131–134] and rhabdomyolysis.[135]

Laboratory Findings and Diagnosis

Pneumococcal infection can be confirmed by isolation of the organism from culture of blood or another normally sterile site; specimens for culture should be obtained, whenever possible, before antimicrobial therapy is initiated. Specimens should be inoculated into culture media immediately or, if delay in processing is unavoidable, stored in nutrient media at 4°C. Blood culture results usually are positive within 18 hours of inoculation.[82]

Gram stain of infected body fluids also should be performed because the finding of gram-positive diplococci suggests a pneumococcal origin. In patients with fulminant infection, organisms can be seen on microscopic examination of a stained smear of buffy coat of peripheral blood, thus reflecting a high concentration of circulating organisms.

Early in vitro PCR studies demonstrated a lack of sufficient sensitivity or specificity to be useful clinically.[136–138] More recently, sensitive real-time PCR-based assays have been developed that allow for accurate detection of *S. pneumoniae*. In a study of children with community-acquired pneumonia (CAP), PCR was significantly more sensitive than culture in revealing bacteremic pneumonia.[139] In another study of adult CAP, PCR was more sensitive than routine blood culture in identifying pneumococcal pneumonia, and a positive blood PCR result was associated with higher rates of mortality, risk for shock, and the need for mechanical ventilation in adults.[140] Studies also have demonstrated the utility of PCR for identifying pneumococci in pleural fluid.[12,13,141]

In the absence of a positive culture or PCR result, definitive diagnosis of pneumococcal pneumonia is difficult. In adults and older children, culture and Gram stain of expectorated sputum can be useful. Lower respiratory tract secretions can be obtained by tracheal aspiration through a catheter or protected brush or by bronchoalveolar lavage. Bronchoalveolar lavage is warranted in children in whom microbiologic diagnosis is essential for management. The most accurate test is needle aspiration with culture of infected lung parenchyma, but the procedure is not justified in most children with uncomplicated pneumonia.

Rapid antigen tests for pneumococcal capsular polysaccharide have limited value in the diagnosis of pediatric infections. A urine antigen assay used in children demonstrated high sensitivity for pneumococcal bacteremia and focal pneumonia. However, the rate of false-positive test results among febrile children without identified pneumococcal infection was 15%.[142] In children with suspected bacterial meningitis, rapid antigen tests of CSF have approximately the same yield as does Gram stain,[143] but findings with an immunochromatic test demonstrated better performance using CSF.[144] In children with pleural empyema, the confirmation of a pneumococcal origin can be enhanced by use of latex agglutination or PCR assays performed on pleural fluid.[13,145]

Treatment

Antimicrobial Susceptibility

Historically, pneumococci have been susceptible in vitro to penicillins, cephalosporins, macrolides (including erythromycin, clarithromycin, and azithromycin), clindamycin, rifampin, vancomycin, and trimethoprim-sulfamethoxazole. Chloramphenicol and sulfonamides have moderate activity. In the early 1990s, pneumococcal strains resistant to penicillin and other agents emerged and increased. Associated with the introduction of PCV7 in 2000 and a change in definition of nonsusceptibility, antimicrobial resistance decreased during the first decade of the 21st century.

Isolates of *S. pneumoniae* are tested by broth dilution assays or E tests (AB Biodisk NA, Piscataway, NJ), which provide specific susceptibility data. Interpretive definitions are recommended by the Clinical Laboratory Standards Institute.[146] Nonsusceptible isolates are subdivided into intermediate and resistant strains. Most strains of penicillin-nonsusceptible pneumococci have a minimal inhibitory concentration of <2 µg/mL. However, in the late 1990s strains of *S. pneumoniae* with a minimal inhibitory concentration of >8 µg/mL emerged.[147] In 2002, definitions of susceptibility and nonsusceptibility for penicillin, cefotaxime, and ceftriaxone were revised, resulting in a decrease in nonsusceptibility rates (Table 123.2).[146]

TABLE 123.2

Comparison of Former and New Breakpoints of Antimicrobial Agents (Minimum Inhibitory Concentrations) for *Streptococcus pneumoniae*, by Susceptibility Category: Clinical and Laboratory Standards Institute, 2008

Standard	Susceptibility Category MIC (μg/mL)

	Susceptible	Intermediate	Resistant
PENICILLIN			
Former breakpoints (all clinical syndromes and administered route)	≤0.06	0.12–1	≥2
New breakpoints (by clinical syndrome and administered route)			
Meningitis, IV penicillin	≤0.06	—[a]	≥0.12
Nonmeningitis, IV penicillin	≤2	4	≥8
Nonmeningitis, oral penicillin	≤0.06	0.12–1	≥2
CEFOTAXIME OR CEFTRIAXONE			
Former breakpoints (all clinical syndromes and administered route)	<0.5	1.0	≥2.0
New breakpoints (by clinical syndrome and administered route)			
Meningitis	<0.5	1.0	≥2.0
Nonmeningitis	≤1.0	2.0	≥4.0

[a] No intermediate category for meningitis under new penicillin breakpoints.

IV, intravenous; MIC, minimal inhibitory concentration.

From Clinical and Laboratory Standards Institute (CLSI). Performance Standards for Antimicrobial Susceptibility Testing; 18th Informational Supplement. CLSI document M100-S20. Wayne, PA: Clinical and Laboratory Standard Institute; 2008.

The mechanisms of antibiotic resistance of pneumococci are determined genetically and are shown in Table 123.3.[148–155] Most strains of penicillin-resistant pneumococci also are resistant to other antimicrobial agents. Penicillin resistance correlates directly with resistance to broad-spectrum cephalosporins. Strains that are more resistant to cefotaxime or ceftriaxone than to penicillin are rare.[148]

TABLE 123.3

Mechanisms of Antimicrobial Resistance in *Streptococcus pneumoniae*

Agent	Mechanism of Resistance (Proven or Suspected)
Penicillins and cephalosporins	Alterations in penicillin-binding proteins lead to a decreased affinity between penicillin-binding protein and the β-lactam drugs
Macrolides	Acetyltransferase expression of a ribosomal methylase encoded by the *ermAM* gene (MLS_B phenotype) is responsible for high-level macrolide and chloramphenicol resistance and complete cross- resistance with clindamycin
	Efflux of macrolide from cells, encoded by the *mefE* gene (M phenotype) is responsible for low-level resistance and has no effect on susceptibility to clindamycin
Trimethoprim	Affinity of trimethoprim for its target enzyme (dihydrofolate reductase) is reduced
Quinolones	Reduced affinity of DNA gyrase leads to increased drug concentrations needed to obtain the same degree of enzyme inhibition, or active efflux of drug out of the bacterial cell occurs
Linezolid	Mutations and deletions near the linezolid binding pocket within the *rplD* gene lead to decreased affinity[153]
Carbapenems	Stepwise alterations in penicillin-binding proteins lead to a decreased affinity

	of PB1a, PB2x, and PBP26 to carbapenems[154,155]

The more common is the macrolide resistance phenotype. Oxazolidinones (e.g., linezolid) and lipopeptides (e.g., daptomycin) have demonstrated in vitro and clinical efficacy against resistant *S. pneumoniae*.[151,152] Thus far only 2 invasive *S. pneumoniae* isolates nonsusceptible to linezolid have been identified in the US.[153] Although rare, *S. pneumoniae* resistance to the carbapenems has been reported. Unlike with other β-lactam agents, carbapenem resistance is not easily selected for by exposure to carbapenem.[154,155]

The CDC conducts population-based surveillance through the Active Bacterial Core surveillance (ABCs) to monitor drug resistance in the US. Data are available at www.cdc.gov/abcs/index.html. In 1998, 14% to 16%[156,157] of *S. pneumoniae* isolates were nonsusceptible to one or more antimicrobial agents tested; this percentage increased to 22% by 2002 and 2003.[67,158] However, comparing 1998 to 1999 with 2008, penicillin-nonsusceptible IPD rates declined 64% among children <5 years of age (from 12.1 to 4.4 cases per 100,000), and 45% for adults >65 years of age (from 4.8 to 2.6 cases per 100,000).[159] Following the introduction of PCV7 and PCV13 in 2000 and 2010, the proportion of nonsusceptible pneumococci in children to penicillin and third-generation cephalosporins decreased (Fig. 123.2).[67] The reduction in single and multidrug resistance likely reflects both the reduction in pneumococcal colonization following PCV7 and PCV13 and the reduction in use of antimicrobial agents (Table 123.4).[160,161]

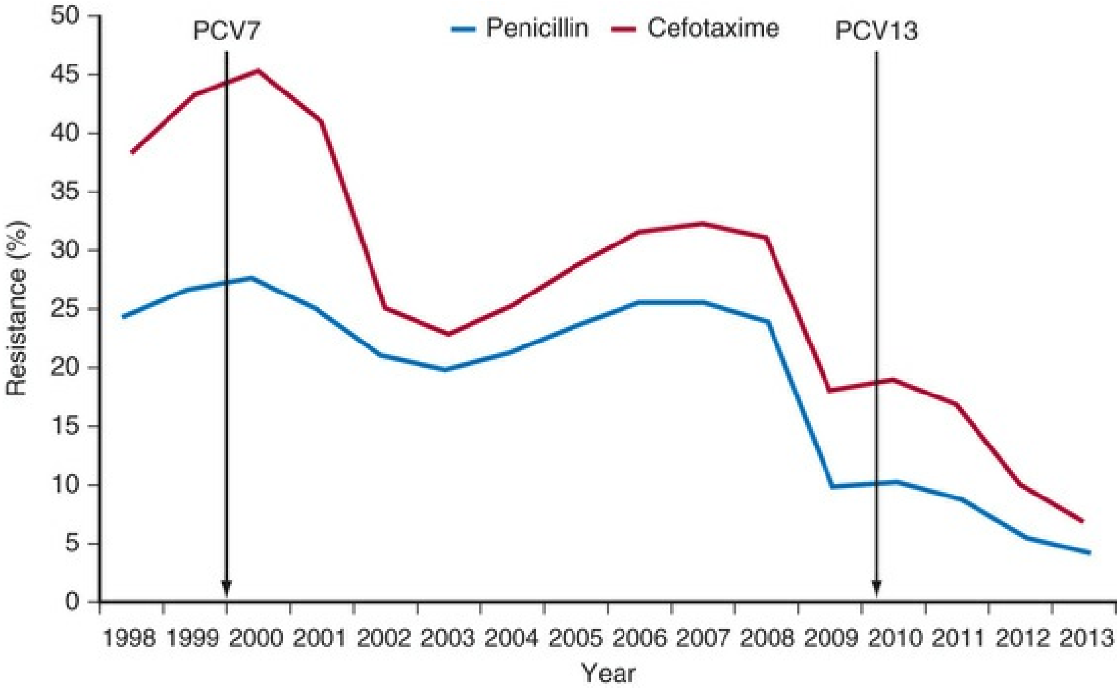

FIGURE 123.2 **Proportion of invasive *Streptococcus pneumoniae* isolates nonsusceptible to penicillin and cefotaxime from 1998 through 2013. [a] Based on 3691, 3499, 3743, and 2870 isolates in the years 2000, 2005, 2009, and 2013, respectively, using the Clinical and Laboratory Standards Institute definitions.

From the Centers for Disease Control and Prevention. Active Bacterial Core Surveillance Report: Emerging Infections Program Network. *Streptococcus pneumoniae.* www.cdc.gov/abcs/reports-findings/surv-reports.html.

Before PCV7 licensure, risk factors associated with multidrug-resistant pneumococcal nasopharyngeal carriage and disease were age <5 years, white race,[157,162] out-of-home childcare in the previous 3 months,[50] recent antimicrobial treatment,[50,163] and residence in a community with high use of antibiotics.[164] With widespread use of PCV7, antimicrobial resistance of emerging non-PCV7 serotypes to penicillin increased; childcare attendance, upper respiratory tract infection, and the presence of young siblings are important predictors.[160,165,166] Thus far, although widespread use of PCV13 has been associated with an increase in nasopharyngeal colonization with non-PCV13 serotypes in young children, the proportion of resistant *S. pneumoniae* organisms isolated from the nasopharynx of children who have received PCV13 has declined.[167,168]

Antimicrobial Therapy

Acute Otitis Media.

In guidelines published by the American Academy of Pediatrics and the American Academy of Family Physicians in 2004, amoxicillin at a dosage of 80 to 90 mg/kg/day in 2 divided doses is the first choice in uncomplicated AOM.[169] This dosing regimen results in concentrations of drug in the middle ear sufficient to eliminate most penicillin-nonsusceptible (resistant) strains.[170] When amoxicillin fails, alternatives include amoxicillin-clavulanate (14 : 1 formulation) in a dosage of 80 to 90 mg/kg/day of the amoxicillin component in 2 divided doses. This regimen (which has activity against β-lactamase–producing organisms, but not enhanced activity against pneumococcus) was demonstrated to be superior to placebo for children 6 through 23 months of age with AOM.[171] Cefdinir (14 mg/kg/day in 1 or 2 doses), cefuroxime axetil (30 mg/kg per day in 2 divided doses), cefpodoxime (10 mg/kg/day in 2 divided doses), and ceftriaxone (50 mg/kg, administered intramuscularly once) are alternatives.[169] Clindamycin and azithromycin are preferred agents for AOM in children who have severe penicillin allergy. The recommended duration for therapy for children <2 years of age with uncomplicated and mild to moderate AOM is 10 days; children 2 to 5 years of age can be treated for 7 days, and for children >6 years of age, a 5- to 7-day course is adequate.[79,169] Tympanocentesis and myringotomy should be considered in the child whose condition is toxic and in whom AOM has shown poor response to initial therapy, to determine bacteriologic features and antimicrobial susceptibility.

Meningitis.

The preferred empiric regimen for initial therapy of infants and children with suspected bacterial meningitis is vancomycin (60 mg/kg/day in 4 divided doses) in addition to ceftriaxone (100 mg/kg/day in 1 or 2 doses) or cefotaxime (300 mg/kg/day in 3 or 4 divided doses).[79] Specific meningitis susceptibility breakpoints for penicillin for pneumococcal meningitis must be applied (see Table 123.2). If *S. pneumoniae* is identified as the etiologic agent and is susceptible to penicillin, vancomycin should be discontinued, and penicillin G (250,000 to 400,000 U/kg/day in 4 or 6 divided doses), ceftriaxone (100 mg/kg/day in 1 or 2 divided doses), or cefotaxime (300 mg/kg/day in 3 or 4 divided doses) should be given.[172] If the pneumococcal isolate is not susceptible to penicillin (intermediate or resistant) but is susceptible to ceftriaxone and cefotaxime, vancomycin can be discontinued, and ceftriaxone or cefotaxime should be continued. If the isolate is nonsusceptible to penicillin, ceftriaxone, and cefotaxime (intermediate or resistant), vancomycin in addition to ceftriaxone or cefotaxime is continued, and rifampin (20 mg/kg/day in 2 divided doses) can be added.[173] No human data are available to determine the treatment of ceftriaxone-resistant pneumococcal meningitis, but results from a rabbit model indicate more rapid elimination of organisms with vancomycin in addition to ceftriaxone than with vancomycin alone.[174] The duration of therapy in uncomplicated cases of pneumococcal meningitis is 10 days.

Adjunctive therapy with dexamethasone has been demonstrated to decrease the incidence of neurologic and audiologic sequelae in children with meningitis caused by *H. influenzae* type b. Although benefit in patients with pneumococcal meningitis has been debated,[175–177] a meta-analysis of randomized clinical trials indicated that dexamethasone significantly reduces the incidence of severe hearing loss in pneumococcal meningitis and also may possibly be effective in preventing hearing or neurologic deficit, provided that dexamethasone is initiated with or before antibiotic therapy.[178] A Cochrane review concluded that the use of dexamethasone at 0.6

mg/kg daily, given before or with the first dose of antibiotics, in children with acute bacterial meningitis including *S. pneumoniae* infection in high-income countries was beneficial by decreasing mortality rates, although the strength of the evidence was not optimal.[177] As a result, the American Academy of Pediatrics recommended that dexamethasone can be considered in the initial therapeutic regimen for infants and children 6 weeks old and older with possible pneumococcal meningitis.[79] Dexamethasone dosage should be 0.15 mg/kg every 6 hours for 48 hours. A repeat lumbar puncture should be considered at 24 to 48 hours of therapy to help guide further therapy if the organism is penicillin nonsusceptible, dexamethasone has been used, or the clinical response is not optimal.

Pneumonia.

In 2011, the Infectious Diseases Society of America and the Pediatric Infectious Diseases Society issued guidelines for the management of pediatric CAP.[179] *S. pneumoniae* was recognized as a common cause of bacterial CAP in children.[93] The guidelines recommend that amoxicillin be used as first-line therapy for outpatient treatment of previously healthy, appropriately immunized infants and preschool-aged and school-aged children with mild to moderate CAP suspected to be of bacterial origin. A daily dose of amoxicillin of 90 mg/kg divided into 3 equal doses is predicted to achieve clinical and microbiologic cure in 90% of children compared with 65% treated with the same daily dose divided into 2 doses.[179] The guidelines recommend the addition of a macrolide agent primarily in school-aged children and adolescents evaluated in an outpatient setting, with findings compatible with those in CAP caused by atypical pathogens.

For hospitalized children, the guidelines recommend that penicillin G (up to 300,000 U/kg/day divided every 4 hours) or ampicillin (up to 400 mg/kg/day divided every 6 hours) be administered to the fully immunized infant or school-aged child admitted to a general medical unit with CAP when local epidemiologic data document a lack of substantial high-level penicillin resistance for IPD caused by *S. pneumoniae*. Empiric therapy with a third-generation parenteral cephalosporin (ceftriaxone or cefotaxime) should be reserved for the following:

hospitalized infants and children who are not fully immunized or in regions where local epidemiology of invasive pneumococcal strains documents high-level penicillin resistance; or hospitalized infants and children with life-threatening infection, including children with empyema.[180]

Prognosis

Death in pneumococcal infection occurs most commonly in immunocompromised hosts, such as patients with SCD, asplenia, patients with congenital or acquired immunodeficiency, and children from developing countries with limited access to medical facilities. With current therapy, the mortality rate from bacterial meningitis in children beyond the neonatal period is ~10%, but neurologic sequelae, including hearing loss and mild to severe motor and intellectual deficits, remain relatively common. In studies of pneumococcal meningitis, 7% to 13% of children died, 29% to 36% had hearing loss at discharge, and 25% to 63% experienced neurologic sequelae.[115–117,181]

Specific pneumococcal serotypes and age have been associated with increased IPD mortality rates. In a study of nearly 19,000 children with IPD in Denmark, 10% of whom were <5 years of age, the overall 30-day mortality rate was 3% in children <5 years of age and 18% in those ≥5 years of age. Compared with serotype 1, which was the most common serotype isolated in Denmark, serotypes 14, 6A, 7F, and 4 were associated with decreased odds of death among children <5 years of age. In contrast, serotypes 31, 11A, 35F, 17F, 3, 16F, 19F, 15B, and 10A were associated with increased odds of death among children ≥5 years of age.[182]

Children with pneumococcal otitis media uncommonly have suppurative complications, such as chronic suppurative otitis media, mastoiditis, petrositis, labyrinthitis or brain abscess, and meningitis. However, since the introduction of PCV7, one large children's hospital reported an increase in pneumococcal mastoiditis caused by multidrug-resistant serotype 19A.[183]

Prevention

Vaccine

The morbidity and mortality of pneumococcal infection in the antibiotic era led to the development and licensure in 1977 of a polyvalent polysaccharide vaccine in the US. The currently available 23-valent pneumococcal polysaccharide vaccine (PPSV23) is composed of purified capsular polysaccharide antigens of 23 serotypes that offered some protection against ~90% of the serotypes causing IPD in the US between 1998 and 1999, 84% by 2006 and 2007,[27,59] and 68% by 2010 and 2013[34] in children <5 years of age. Whereas PPSV23 elicits type-specific antibody responses in most healthy adults and children >5 years of age, the serologic response to the polysaccharide antigens generally is poor in children <2 years of age.[184] PPSV23 is recommended to be given following receipt of PCVs (which should include ≥1 dose of PCV13) to children ≥2 years of age with underlying conditions (see Table 123.1). The interval between PCV13 and PPSV23 is ≥8 weeks. A second dose of PPSV23 is given once ≥5 years after the first.[79,185]

The conjugate vaccines (PCVs) in which purified capsular polysaccharides of different pneumococcal serotypes are covalently bound to a protein carrier are immunogenic in infants at 2 months of age, induce B-lymphocyte memory cells resulting in an anamnestic response with subsequent doses, and reduce carriage of vaccine serotypes.

The PCV7 (Prevnar-7 Pfizer, New York, New York) vaccine was approved in 2000 for universal infant immunization in a 4-dose schedule in the US.[59,77] PCV7 contains the polysaccharides of serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F; these serotypes accounted for the majority of cases of IPD and AOM cases in US children <6 years of age during the period 1978 to 1994.[59] Infants respond to each PCV type with substantial concentrations of serum antibody believed to be protective against invasive disease.[186] Protective titers are achieved after doses administered at ages 2, 4, and 6 months but wane during the following 6 months, thus requiring a booster dose at 12 to 15 months of age.

Efficacy of PCV7 was demonstrated in prospective, randomized clinical trials in northern California[186] and in Finland.[5] In a large randomized study, PCV7 was somewhat efficacious against placement of tympanostomy tubes, AOM episodes, and related office visits; it was moderately efficacious against pneumonia; and it was highly efficacious in preventing IPD.[186,187] Adverse events were limited to mild erythema, induration, and tenderness at the injection site, and fever (39°C or greater) in approximately 1% to 2% of recipients.[186]

PCV7 was recommended by the American Academy of Pediatrics and CDC in 2000 for all infants in a 4-dose schedule at ages 2, 4, 6, and 12 to 15 months.[59,77] In 2007, the Advisory Committee on Immunization Practices revised recommendations to include routine use in all children 2 through 59 months of age.[188] Studies demonstrated the effectiveness of PCV7 when the vaccine was given in different and abbreviated schedules from that of the 4 doses recommended in the US.[189,190] Surveillance through the Vaccine Adverse Event Reporting System, a US passive database, confirmed the safety of PCV7.[191]

By December 2010, more than 300 million doses of PCV7 had been distributed worldwide; most of the doses were distributed in the US.[192] Following the introduction of PCV7, a significant decline was reported in the burden of IPD, pneumonia, meningitis, and AOM, as well as a decreasing incidence of pneumococcal penicillin resistance.[193–197] The CDC ABCs reported that the incidence of IPD in children <5 years of age decreased from 97.6 cases to 21.8 cases per 100,000 population from 1999 to 2009, a decrease of >80%.[67,198] Indirect effects of PCV7 were demonstrated by declines in IPD in other age groups in whom the PCV7 was not indicated (Table 123.5).[24,27] Comparable decreases in IPD also were reported in other countries using PCV7.[199,200] Decreases in IPD were greatest among children <12 months and 12 to 23 months of age.[27] Further decreases occurred after introduction of PCV13 in 2010. The incidence of IPD decreased by 49%, from 19 cases to 9.6 cases per 100,000 from 2010 to 2013 in children <5 years of age, with the greatest reduction among children <2 years of age (Fig. 123.3).[67]

TABLE 123.5

Changes in Incidence of Invasive Pneumococcal Disease by Age and Serotype, 1998 to 1999 Average (Baseline) Versus 2007

Age Group (Yr)	Serotype	Incidence (Cases Per 100,000 Population)	Change in Rate (2007 vs. Baseline)

		1998–1999 (n = 4,048)	2007 (n= 2,576)	Change (%) (95% CI)
<5	All types	98.7	23.6	−76 (−79 to −73)

From Pilishvili T, Lexau C, Farley MM, et al. Sustained reductions in invasive pneumococcal disease in the era of conjugate vaccine. J Infect Dis 2010;201:32–41

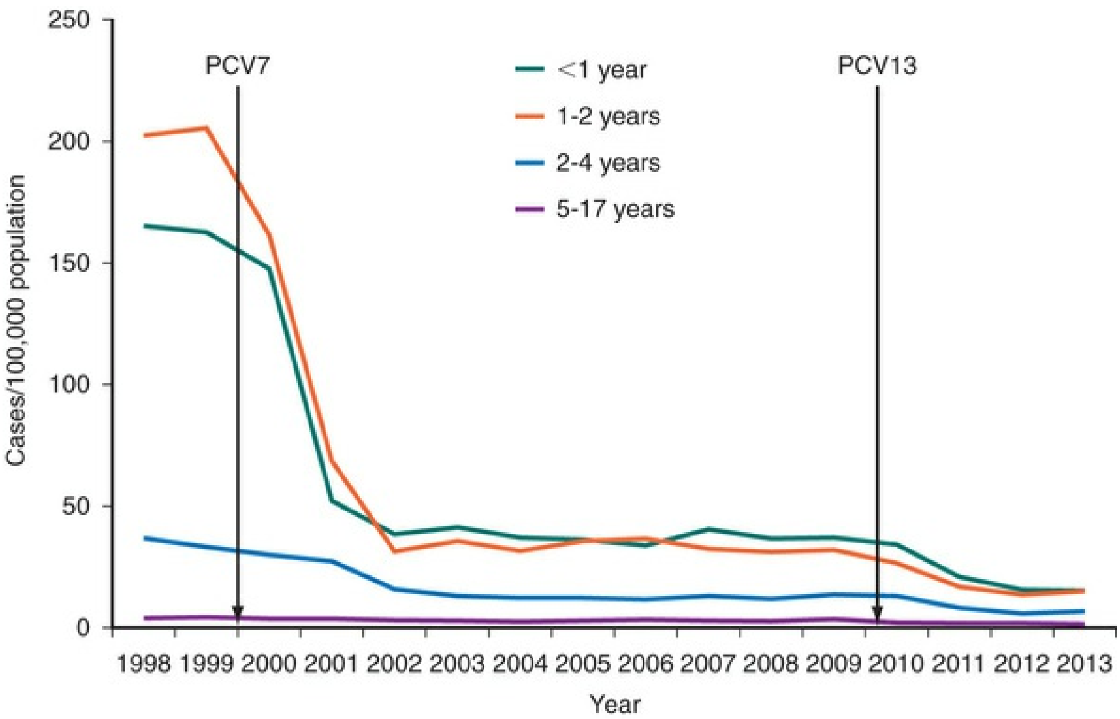

FIGURE 123.3 **Rates of invasive pneumococcal disease among children younger than 18 years old, according to age and year. PCV7, 7-valent pneumococcal conjugate vaccine; PCV13, 13-valent pneumococcal conjugate vaccine.** (Data from Centers for Disease Control and Prevention. Active Bacterial Core Surveillance From 1998 Through 2013. www.cdc.gov/abcs/reports-findings/surv-reports.html.)

Some regions in the US (including Alaska and Utah) and other regions of the world reported a less dramatic decrease in IPD following the introduction of PCV7 and the early emergence of IPD caused by non-PCV7 serotypes.[25,26,86,105,141] By 2007, non-PCV7 serotypes 19A, 3, 7F, 15B/C, 22F, and 33F were the most common serotypes causing IPD among children <5 years of age in the US.[25,27,201,202] In many regions in the US, serotype 19A emerged as the leading cause of IPD during the PCV7 era; by 2007 to 2008, serotype 19A accounted for 46% of 369 non-PCV7 isolates, whereas serotypes 1, 3, and 7F combined accounted for 22%.[29] In Massachusetts, serotype 19A increased from 10% of IPD cases in 2002 to 41% in 2006.[203] A similar trend also was noted in Texas, where significant increase in infections with serotype 19A were noted between 1999 and 2008.[204]

S. pneumoniae bacteremia without focus, pneumonia, and meningitis decreased significantly following PCV7 licensure.[83,205] Data from the Nationwide Inpatient Sample database demonstrated a sustained 33% decrease in hospitalized children with pneumonia <2 years of age in the PCV7 era (2001–2007) compared with 1996 to

1999.[206] By 2009, a 43% decline in all-cause pneumonia among US children <2 years of age was reported.[207] Similarly, pneumococcal meningitis decreased. Data from the CDC ABCs sites showed a 64% decrease in incidence of pneumococcal meningitis from 4.7 cases to 1.7 cases per 100,000 population between 1998 to 1999 and 2006 to 2007 among children <5 years of age. This decrease was primarily the result of a 97% (from 3.8 to 0.1 cases per 100,000 population) decline in meningitis caused by PCV7seroypes.[27] However, the incidence of pneumococcal meningitis caused by non-PCV7 types, although low, increased 78% (from 0.9 to 1.6 cases per 100,000 population) over the same time period.[27] The largest decline in meningitis occurred in children <2 years of age, and moderate decreases occurred in other age groups not eligible for PCV7.[27,201,208] Similar decreases were noted in national trends in rates of hospitalization for pneumococcal meningitis, by using data from the Nationwide Inpatient Sample and from other countries where PCV7 was used widely.[201,209–212] By 2007, >94% of pneumococcal meningitis cases in the US were caused by non-PCV7 types.[27,201] In a retrospective study of pneumococcal meningitis in 8 children's hospital in the US from 2007 through 2009, 54% of pneumococcal meningitis cases were caused by PCV13 types, with serotypes 19A, 7F, and 3 accounting for >90% of isolates.[116] During the PCV7 era, many sites in the US and Europe reported significant increases in pneumococcal empyema.[11,102–106,213] Li and Tancredi[103] showed a 70% increase in pneumococcal empyema in the US from 2.2 per 100,000 in 1997 to 3.7 per 100,000 children in 2006 in patients <18 years of age. The largest increase was among children <5 years of age. Similarly Grijalva and colleagues[104] noted a twofold increase in hospitalizations for pneumonia complicated by empyema from 3.5 cases per 100,000 children in 1996 to 1998 to 7.0 cases per 100,000 children in 2005 to 2007.

In 2010, the 13-valent pneumococcal polysaccharide-protein conjugate vaccine (PCV13 [Prevnar 13], Pfizer, New York, New York) was approved by the US Food and Drug Administration for prevention of IPD in infants and young children 6 weeks through 71 months of age. PCV13 contains the 7 serotypes included in PCV7 and 6 additional serotypes (1, 3, 5, 6A, 7F, and 19A). PCV13 replaces PCV7.[214,215] PCV13 also is approved for the prevention of AOM caused by the 7 serotypes also covered by PCV7. PCV13 was licensed by the US Food and Drug Administration and elsewhere on the basis of studies demonstrating safety and immunogenicity.[216,217] By 2013, the US national vaccination coverage among children 19 to 35 months of age was 92% for ≥3 PCV13 doses and 82% for ≥4 PCV13 doses.[218]

The epidemiology of IPD since the introduction of PCV13 continues to change. Data from the CDC ABCs sites show a 64% (95% interval estimates, 59%–68%) decrease in the incidence of IPD, when the projected incidence of IPD in 2013 was compared during the period 2004 to 2010. The decline primarily reflects a 93% decrease in IPD caused by the additional 6 serotypes in PCV13. A reduction in IPD in the US has been observed in all age groups.[34] Similar decreases also have been reported in countries where PCV13 has been introduced.[219–222]

A large database of US hospital discharges coded according to the International Classification of Diseases, Ninth Revision (ICD-9) showed a decline in IPD, empyema, all-cause pneumonia, and noninvasive pneumococcal or lobar pneumonia in 2011 to 2012 compared with 2007 to 2009.[101] The declines were among children <2 years of age who were discharged with IPD (64%), empyema (50%), all-cause pneumococcal pneumonia (21%) and noninvasive pneumococcal pneumonia (40%). Similarly, among children 2 to 4 years old, decreases were observed in IPD (55%), empyema (46%), and all-cause pneumococcal pneumonia (17%); as well as empyema (37%) in children 5 to 17 years of age. Among children, the prevalence of pneumonia is reduced compared with that of other IPD syndromes. Potential explanations of differential effects include individual serotypes that could predispose children to specific syndromes and differential effectiveness among children with and without underlying disorders.[101]

Before the introduction of the PCV13 in the US, >95% of cases of IPD in children were caused by serotypes not covered by the PCV7 vaccine, primarily serotypes 19A, 7F, 3, and 1. Three years after the introduction of PCV13, IPD caused by serotypes 19A and 7F declined, significantly with no significant change in infection with serotype 3 (which was associated with reduced immunogenicity in clinical trials of PCV13).[216] By 2013, 69% of cases of IPD in children <5 years of age were caused by non-PCV13 serotypes (Table 123.6). Overall, the most common serotypes currently isolated from patients <18 years old who have IPD are serotypes 22F, 33F, 38, 35B, 15B, 19A, 15C, 3, 23B, and 12F, whereas serotypes 22F, 3, 7F, 19A, 6C, 12F, 33F, 35B, 16F, and 9N are the most common isolates from adults.[34] The impact of PCV13 in groups targeted and not targeted for vaccination also has been observed in France, Denmark, and Norway.[220–222]

Meningitis	1,078/19,222 (6%)	533/8,188 (7%)	—

[a] Data are number (%) or n/N (%). Some percentages do not total 100 because of rounding.

[b] July 2004 through June 2010.

[c] July 2010 through June 2013.

[d] Based on Advisory Committee on Immunization Practices recommendations for children and adults.[33,228–230]

[e] PCV7 types consist of 4, 6B, 9V, 14, 18C, 19F, 23F, and 6A. PCV13 minus PCV7 types consist of 1, 3, 5, 7F, and 19A. PPSV23 minus PCV13 types consist of 2, 8, 9N, 10A, 11A, 12F, 15B, 17F, 20, 22F, and 33F.

IPD, invasive pneumococcal disease; PCV7, 7-valent pneumococcal conjugate vaccine; PCV13, 13-valent pneumococcal conjugate vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine.

From Moore MR, Link-Gelles R, Schaffner W, et al. Effect of use of 13-valent pneumococcal conjugate vaccine in children on invasive pneumococcal disease in children and adults in the USA: analysis of multisite, population-based surveillance. Lancet Infect Dis 2015;15:301–309.

The safety and adverse reactions after administration of PCV13 in clinical trials were assessed in 3 clinical trials in the US. Injection-site reactions, fever, decreased appetite, irritability, and increased or decreased sleep were solicited adverse reactions reported in ≥20% of subjects. The incidence and severity of solicited local reactions at the injection site (pain, tenderness, erythema, and induration or swelling) and solicited systemic reactions (irritability, drowsiness or increased sleep, decreased appetite, fever, and restless or decreased sleep) were similar in the PCV13 and PCV7 groups.[223]

In the first 3 years following PCV13 introduction in the US, an estimated 10,000 cases of IPD in children and 20,000 cases in adults were prevented. Investigators also estimated that 3000 deaths, 97% in adults, likely were prevented.[34] Ongoing surveillance of pneumococcal diseases, serotypes, clinical syndromes and ages of affected children will be critical to understand the remaining burden and emerging epidemiology of pneumococcal disease and serotypes, to guide national vaccine policy.

Passive Immunoprophylaxis

Immune globulin reduces the incidence of pneumococcal and other bacterial infections in several circumstances. In a placebo-controlled trial in HIV-infected children with clinical or immunologic evidence of disease, children given immune globulin intravenous (400 mg/kg given every 28 days) had a longer time before serious bacterial infection and a smaller number of infections compared with the control group.[224] The benefit primarily was in preventing IPD and clinically diagnosed acute pneumonia. Recommended management includes immune globulin intravenous therapy for HIV-infected children who have both recurrent serious bacterial infections despite appropriate antimicrobial prophylaxis and humoral immunodeficiency.[225]

Chemoprophylaxis

For prevention of IPD in children with functional or anatomic asplenia, particularly SCD, daily antimicrobial prophylaxis with oral penicillin V or G (125 mg twice daily for children <5 years of age; 250 mg twice daily for children >5 years of age) is recommended.[77] A chemoprophylactic regimen of penicillin reduced the incidence of IPD by 84% in a randomized, placebo-controlled trial in children with SCD.[226] These data are the basis of the recommendation to give daily penicillin prophylaxis to these patients beginning before 2 months of age or as soon as the diagnosis is made.[77] Prophylactic penicillin can be discontinued in children with SCD after 5 years if they have not experienced IPD and have received all recommended pneumococcal immunizations.[227] The duration of prophylaxis for children with asplenia from other causes is unknown. Some experts continue prophylaxis throughout childhood.[225]

Prevention of Disease in Contacts

Because secondary cases of IPD are uncommon, chemoprophylaxis is not indicated for contacts of patients with such infections.[225] Universal precautions are recommended for hospitalized patients with IPD, and droplet precautions are recommended for infants and children with presumed bacterial meningitis for the first 24 hours of therapy because of the possibility of infection with pathogens other than *S. pneumoniae* such as *Neisseria meningitidis* or *H. influenzae* type b.

Key Points

Diagnosis and Management of *Streptococcus pneumoniae* Infection

Microbiology

- These catalase-negative, gram-positive cocci appear as lancet-shaped diplococci on Gram stain.
- These facultative anaerobic organisms have enhanced growth in 5% carbon dioxide.
- Organisms exhibit α hemolysis on blood agar and can be identified presumptively from their susceptibility to optochin.
- This capsular polysaccharide results in >90 immunologically distinct serotypes within 45 serogroups.
- Alterations in penicillin-binding enzymes result in penicillin and cephalosporin resistance.

Epidemiology

- It is part of the normal oropharyngeal flora, with the highest prevalence (~35%) in preschool-aged and school-aged children.
- Invasive pneumococcal disease is highest among children <2 years of age.
- History of antecedent upper respiratory tract illness suggests that disruption of mucosal barrier leads to bloodstream invasion.
- *S. pneumoniae* has a predilection for pulmonary or meningeal focus.

Diagnosis

- Recovery from blood culture is enhanced by immediate inoculation of specimen into an automated blood culture system.
- Polymerase chain reaction can detect *Streptococcus pneumoniae* DNA in blood and pleural fluid.
- Gram stain of infected sterile body fluid with findings of lancet-shaped gram-positive diplococci suggests a pneumococcal origin.

Treatment

- Penicillin is drug of choice for penicillin-susceptible *S. pneumoniae* isolates.
- *S. pneumoniae* is susceptible generally to cephalosporins, carbapenems, vancomycin, clindamycin, and levofloxacin.

Duration of Therapy

- Response to therapy is usually rapid.
- Duration of therapy depends on the site of infection.

Prevention

- Widespread use of pneumococcal conjugate vaccines (PCV7, PCV10, and PCV13) have resulted in substantially decreased rates of invasive pneumococcal disease in children and adults.

PCV7, 7-valent pneumococcal conjugate vaccine; PCV10, 10-valent pneumococcal conjugate vaccine; PCV13, 13-valent pneumococcal conjugate vaccine.

Acknowledgments

We acknowledge the contributions of Georges Peter, MD, and Jerome O. Klein, MD, for their work on this chapter in the previous edition.

Other Gram-Positive, Catalase-Negative Cocci

Leuconostoc and *Pediococcus* Species and Other Genera

David B. Haslam, Joseph W. St. Geme III

Characteristics of Pathogens

Among the gram-positive, catalase-negative cocci, streptococci and enterococci cause most human infections. The remaining organisms belong to 5 genera that can be identified according to the criteria proposed by Facklam and colleagues[1] (Table 124.1), and they form colonies that are α hemolytic or nonhemolytic on sheep blood agar and are easily confused with *Streptococcus pneumoniae* or viridans streptococci. These organisms appear to lack typical virulence determinants and consequently are uncommon pathogens.

Adapted from Facklam R, Hollis D, Collins D. Identification of gram-positive coccal and coccobacillary vancomycin-resistant bacteria. J Clin Microbiol 1989;27:724–730.

Of these genera, *Leuconostoc* and *Pediococcus* account for most human infections and are notable for their intrinsic high-level resistance to vancomycin. The genus *Leuconostoc* consists of 6 species, of which *L. mesenteroides* and *L. paramesenteroides* are most commonly associated with pediatric infections. The genus *Pediococcus* consists of 8 species, but only *P. acidilactici* and *P. pentosaceus* are recognized as potential pathogens.

Epidemiology

Leuconostocs and pediococci are found on certain foods, including vegetables, dairy products, and processed meats. Occasionally they can be isolated from culture of vaginal and gastrointestinal tract specimens. Leuconostocs can colonize other mucosal surfaces as well, including gastrostomy and tracheostomy sites. Pediococci are components of some probiotic preparations.

Clinical Manifestations

Leuconostoc Species.

Invasive disease caused by *Leuconostoc* spp. is unusual, with approximately 20 cases reported in children. Most infants with systemic infection have an underlying disorder, such as prematurity or a gastrointestinal abnormality.[2] Rarely, however, bloodstream infection can occur in otherwise normal infants.[3] Older children with *Leuconostoc* infection typically have an immunodeficiency. In patients of all ages, previous therapy with vancomycin and the presence of an indwelling catheter appear to be additional risk factors. Contaminated enteral feedings, including infant formula, have been implicated as the source of bloodstream infection in isolated cases. An association exists between *Leuconostoc* infection and enteral feeding in patients with short gut syndrome.[3] In many children with underlying gastrointestinal disease, bloodstream infection is polymicrobial and involves *Leuconostoc* in addition to enteric organisms.

Leuconostoc meningitis and pneumonia have been reported in children, almost always in association with an underlying disease such as gastrointestinal disease or immunodeficiency or with an indwelling central nervous system shunt. Other reported infections include peritonitis in a child with an indwelling peritoneal dialysis catheter.

Pediococcus Species.

Few pediatric cases of invasive *Pediococcus* infection have been described.[4] Reported patients have been <1 year of age and have recently undergone operations for gastrointestinal abnormalities. Antibiotic therapy that included a β-lactam agent and an aminoglycoside were effective.[5]

Gemella Species.

Gemella spp. are uncommon causes of pediatric disease. However, endocarditis resulting from *Gemella* is reported occasionally, in one case following body piercing.[6,7] *Gemella* endocarditis can lead to remote infections such as lung or brain abscess.[8]

Other Genera.

Aerococcus viridans is a rare cause of invasive disease in children, associated with <10 cases of meningitis or bacteremia in medical publications.[9] *Weissella* spp. are newly reclassified organisms that previously were misidentified as lactobacilli. Newer molecular diagnostic methods have identified *Weissella* as an occasional cause of bloodstream, bone, and joint infection.[10]

Therapy

Leuconostocs and pediococci have intrinsic high-level resistance to vancomycin (minimum inhibitory concentration [MIC] ≥64 μg/mL). The mechanism of resistance in both genera is unknown but appears to be chromosomally mediated and is distinct from the mechanism demonstrated by vancomycin-resistant enterococci.

Leuconostocs and pediococci are moderately resistant to penicillin, with MICs ranging from 0.03 to 2 μg/mL; 90% of isolates have an MIC <1 μg/mL.[2] Many isolates are tolerant of penicillin (ratio of minimum bactericidal concentration to MIC >32), although the clinical significance is unclear. Penicillin, either alone or in combination with an aminoglycoside, is the treatment of choice for *Pediococcus* and *Leuconostoc* infections. Chloramphenicol, aminoglycosides, and carbapenems also are active against in vitro, but clindamycin, trimethoprim-sulfamethoxazole, and third-generation cephalosporins have unreliable activity. Daptomycin and linezolid both demonstrate good activity against *Leuconostoc* and *Pediococcus* and may be the preferred treatment for invasive infection in immunocompromised patients.[11] *Aerococcus* and *Gemella* spp. are susceptible to penicillin, cephalosporins, erythromycin, and vancomycin; penicillin alone or in combination with an aminoglycoside is the treatment of choice for invasive infection.

Gram-Negative Cocci

OUTLINE

125 Neisseria meningitidis

126 Neisseria gonorrhoeae

127 Other Neisseria Species

125

Neisseria meningitidis

Andrew J. Pollard, Adam Finn

Neisseria meningitidis (meningococcus) is a leading cause of serious bacterial infections in children, most commonly manifesting as purulent meningitis or septicemia. Asymptomatic pharyngeal colonization is more common than invasive disease, and humans are the only reservoir.[1] Gaspard Vieusseux provided the first clinical description of meningococcal disease during an outbreak in Geneva, Switzerland, as recently as 1805,[2] which was followed by epidemics across Europe for the next 50 years. The first description in North America was in Medfield, Massachusetts, in 1806.[3] Further cases appeared in New England and Canada during the following decade. In 1887 Anton Weichselbaum described paired cocci inside white blood cells (WBCs) in cerebrospinal fluid (CSF) and named the organism *Diplococcus intracellularis,*[4] and the organism later was reclassified as *Neisseria meningitidis.*

Microbiology

N. meningitidis is a nonmotile, gram-negative coccus, usually appearing in pairs with abutting sides flattened. The genus *Neisseria* also includes *N. gonorrhoeae* and several commensal organisms, including *N. flavescens, N. lactamica, N. mucosa, N. sicca,* and *N. subflava.*

N. meningitidis has complex nutritional requirements but grows well on chocolate, blood, Mueller-Hinton, trypticase soy, and GC agar in a humidified environment at 35°C to 37°C. *N. meningitidis,* like *N. gonorrhoeae,* requires additional carbon dioxide for growth. The organism is highly susceptible to drying, cold, sunlight, and either high or low pH. *Neisseria* species are differentiated initially by biochemical characteristics. *N. meningitidis* can produce acid from glucose and maltose, but *N. gonorrhoeae* uses maltose alone. All neisseriae produce catalase and are oxidase positive.

The cell envelope of *N. meningitidis* has 3 layers (Fig. 125.1): a cytoplasmic membrane, a peptidoglycan cell wall, and an outer membrane that contains lipopolysaccharide (LPS), phospholipid, and outer membrane proteins(OMPs). Invasive meningococci also have a polysaccharide capsule surrounding the cell envelope that confers the capsular group, often termed the "serogroup," and reflecting the main typing method (i.e., serology, used before the availability of molecular typing). The recent appearance of invasive meningococcal disease in 1805 could indicate the acquisition of capsule genes in the last 200 years that have conferred virulence potential on an organism that previously was only a commensal, as well as survival advantages the precise nature of which remains obscure.

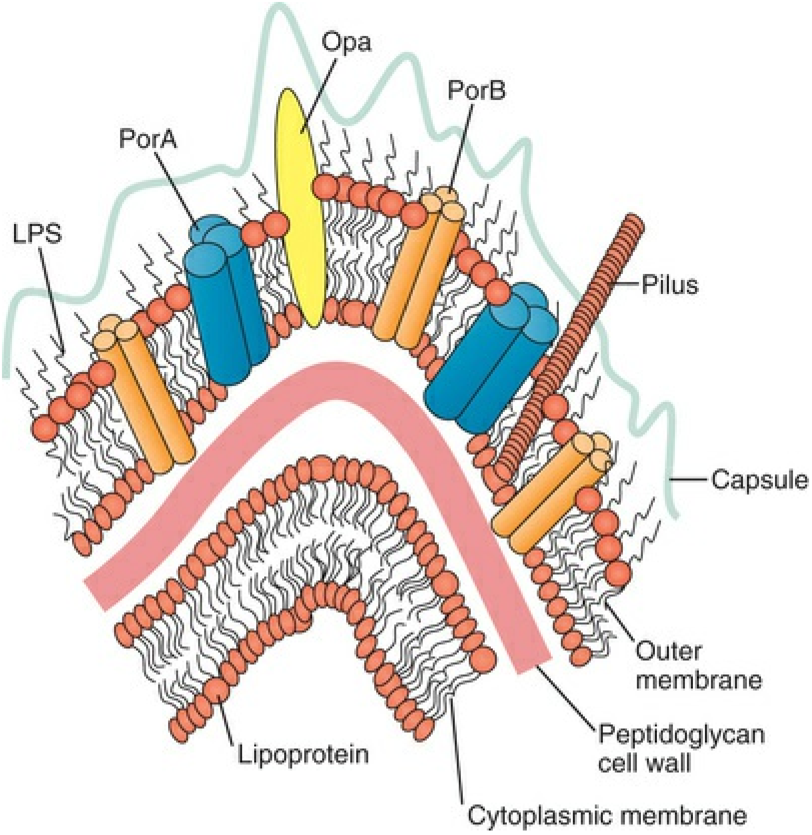

FIGURE 125.1 **Surface structures of *Neisseria meningitidis.* LPS,**

lipopolysaccharide; Opa, PorA, and PorB, outer membrane proteins.

The antigen responsible for capsular group specificity is the capsular polysaccharide. Twelve different capsular groups of meningococci have been identified (A, B, C, X, Y, Z, 29E, W [formerly designated W135], H, I, J, and L), each with different saccharide subunits, but only 5 are commonly associated with disease: A, B, C, Y, and W (Table 125.1).[5] A sixth, capsular group X, has been associated with epidemics in sub-Saharan Africa. The other capsular groups are responsible for occasional sporadic cases, but these groups are isolated from asymptomatic carriers more commonly than from people with disease.

TABLE 125.1

Chemical Structure of Meningococcal Polysaccharide Capsules

Capsular Group	Chemical Structure
A	*N*-acetyl mannosamine-1 phosphate
B	α2-8 NANA
C	α2-9 NANA
29E	3-deoxy-D-manno-octulosonic acid
X	α1-4 *N*-acetyl-D-glucosamine-1 phosphate
W	Copolymer of NANA with galactose
Y	Copolymer of NANA with glucose

NANA, *N*-acetyl neuraminic acid.

Within each capsular group, serotypes and subtypes can be identified on the basis of differences in 2 OMPs, PorB and PorA, respectively, whereas the immunotype is defined by the LPS structure.[6] More recently, sero(sub)typing has been undertaken by molecular methods in view of the limited availability of serologic reagents.[7] With the advent of novel vaccines based on surface proteins, antigen-gene sequence typing is growing in importance to describe diversity and predict potential vaccine coverage. In addition to serologic and genetic differentiation based on surface antigens, related meningococcal isolates previously were described by differences in the electrophoretic mobility of cytoplasmic enzymes (multilocus enzyme electrophoresis [MLEE]) and more recently have been described by the genetic relatedness of strains using multilocus sequence typing (MLST),[8] which defines meningococci using sequence data from 7 housekeeping genes.

Using this method, 7 hyperinvasive lineages have been described that cause most cases of invasive meningococcal disease worldwide. With the availability of low-cost, high-throughput sequencing, routine whole-genome sequencing is now replacing these other typing methods.

Complete genome sequences were determined for several meningococcal isolates in 2000,[9,10] and these isolates were shown to contain a large number of repeating sequences. In addition, meningococcal genomes contain multiple insertion sequences that are responsible for the uptake of DNA from the microbial environment,[11] thus allowing the addition of new genes. For example, meningococci can acquire the capsular operon from another capsular group and switch to expression of the donor gene product (e.g., switch from capsular group B to capsular group C and vice versa).[11,12] Meningococci also import DNA at high rates from other commensal *Neisseria* spp. during mixed colonization in the nasopharynx.[13] Phase variation of surface structures during colonization and invasion can augment the foregoing mechanisms in helping evade host responses. Variability in the expression of immunogenic proteins may be important for persistence of the organism but has hampered vaccine development. However, sequence data from the meningococcal genome have been used to identify genes encoding potential vaccine candidates that are included in the most recent generation of meningococcal vaccines based on surface-expressed proteins.[14,15]

Virulence and Pathogenesis

The rare episodes of invasive meningococcal disease that occur probably do not provide any survival advantage for the meningococcus. It seems likely that the virulence factors associated with pathogenic meningococci have evolved as a result of a fitness advantage that they confer in the transmission-colonization cycle that describes the organism's normal lifestyle and in the polymicrobial environment of the human nasopharynx. The polysaccharide capsule enhances invasiveness by inhibiting phagocytosis but may also be important, for example, for avoiding desiccation during transmission. Immunoglobulin (Ig) A1 protease, a neutral endopeptidase with specific enzymatic activity against human IgA1, appears to enhance the ability of pathogenic *Neisseria* to colonize mucosal surfaces. The ability of pathogenic *N. meningitidis* to survive and multiply within the human host is facilitated by the organism's ability to extract iron from high-affinity iron-binding proteins by means of a non–energy-requiring cell surface mechanism.

Colonization involves a series of interactions between meningococcal surface structures (including pili and the OMP Opa) and specific ligands on the surface of cells in the nasopharyngeal mucosa of the human,[16–18] and it must precede invasive infection. Invasion of *N. meningitidis* through the nasopharyngeal mucosa into the bloodstream is incompletely understood, but it appears to depend on phase variation of meningococcal surface structures, including the capsule, and it results in the release of endotoxin (LPS) contained in blebs formed from the outer membrane during bacterial growth. A cascade of mediators is triggered in an inflammatory storm with interactions between LPS and CD14 and toll-like receptor 4 and between lipoprotein or peptidoglycan and toll-like receptor 2 at the core. The subsequent cytokine release (rather than direct tissue injury by microbial products) is thought ultimately to produce the features of septic shock in susceptible people. High levels of meningococcal LPS are found in severe meningococcal disease and correlate strongly with death.[19] Many different genes are involved in these responses, and various human gene polymorphisms have been associated with susceptibility to meningococcal infection or severity of disease.[20] Early in meningococcal disease high levels of tumor necrosis factor-α (TNF-α), soluble TNF-α receptor (sTNFR), interleukin-1 (IL-1), IL-1ra, IL-1β, IL-6, IL-8, IL-10, plasminogen activator inhibitor (PAI-1), and leukemia-inhibitory factor are detectable in blood, and elevated levels of many of these cytokines also have been associated with disease severity or fatality.[21] Indeed, the balance between these cytokines and their antagonists may influence the outcome of meningococcal disease.[22]

Although during meningococcal meningitis an inflammatory cascade of cytokines also is released in the subarachnoid space, the levels of these cytokines are not obviously associated with death.[23] Nevertheless, the inflammatory response is thought to mediate neurologic injury in meningococcal meningitis and can be suppressed by use of corticosteroids, although clinical data to support use of this adjunctive treatment for meningococcal meningitis are limited.[24,25]

Immunity

In 1918, Matsunami and Kolmer[26] demonstrated that the bactericidal activity of clotted whole blood from various laboratory animals was related to the resistance of these animals to infection with *N. meningitidis.* These investigators also demonstrated that the bactericidal activity of serum from adults was greater than that from children, thus providing the first link between serum bactericidal activity and the susceptibility of young children to meningococcal disease. Soon afterward, Heist and colleagues[27] found individual variation in the bactericidal activity of sera and individual susceptibility to infection. Unfortunately Heist's own serum contained inadequate bactericidal activity against meningococcus to protect him, and he died of invasive meningococcal disease before the publication of these observations.

Goldschneider and associates[28,29] are credited with firmly establishing the importance of the relationship between serum bactericidal activity (defined as killing of meningococci after mixing with serum and exogenous complement in vitro) and susceptibility to infection. These investigators showed in 1969 that susceptibility to invasion by a newly acquired strain of *N. meningitidis* was associated with the absence of bactericidal antibody against that strain,[28,29] an observation reconfirmed in 2000 during an outbreak in the United Kingdom.[30] This finding is further supported by the age-specific incidence of meningococcal disease caused by capsular groups A, B, and C, which correlates inversely with the age-specific prevalence of protective bactericidal antibody (Fig. 125.2).[29,31,32] Titers of antimeningococcal bactericidal antibody in a newborn infant are similar to those in the mother but decline after birth and reach a nadir at about 6 months of age, which correlates with the peak incidence of meningococcal disease at 5 to 9 months of age.

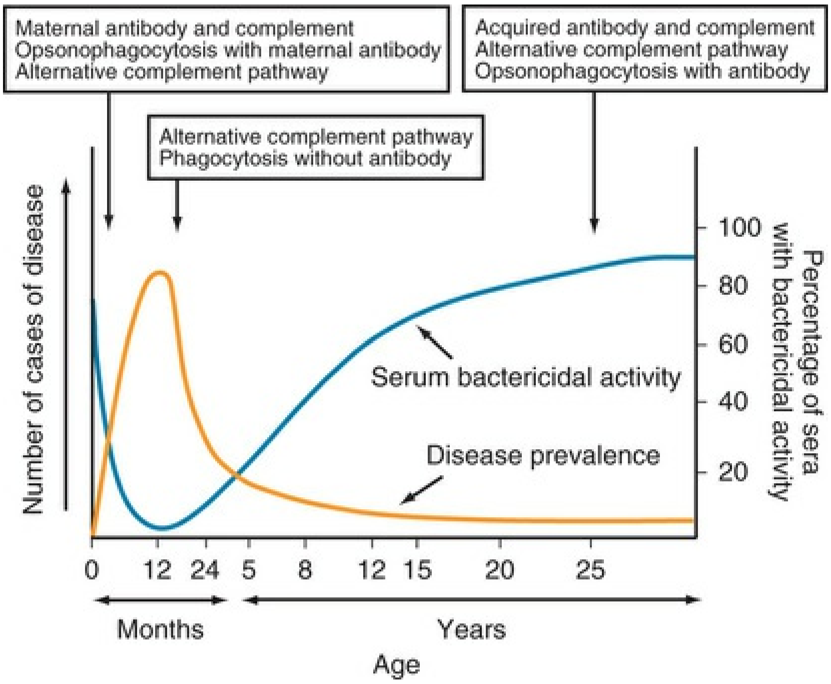

FIGURE 125.2 **Age-specific incidence of meningococcal disease contrasted with serum bactericidal activity.** (Modified from Goldschneider I, Gotschlich E, Artenstein M. Human immunity to the meningococcus. I. The role of humoral antibodies. J Exp Med 1969;129:1307.)

People with hypogammaglobulinemia may have a moderately increased rate of meningococcal infection.[33,34] Conversely, serum therapy was successfully used in the treatment of meningococcal disease before the advent of antibiotics. The mortality rate of untreated meningococcal disease fell from between 60% and 80% following the introduction of therapy using horse serum shortly after 1900 to between 13% and 30% in treated patients, depending on how promptly treatment was initiated.[35]

The bactericidal activity of immune sera requires the presence of both antibody and complement. Approximately 0.3% of patients with meningococcal disease have complement deficiency[36]; 50% of people with a late complement component deficiency (C5–C9) will develop meningococcal disease, and one half of these patients will have recurrent attacks, thus highlighting the importance of complement in defense against meningococcal infection.[37,38] These episodes usually occur in older age groups and often are associated with the less common capsular groups and only rarely with capsular group B disease.[36,39,40] A relative deficiency of late complement components is observed in infancy,[41] and this deficiency may add to the susceptibility to meningococcal infection in this age group. In contrast to people with terminal complement component deficiency, susceptible complement-deficient people who have either properdin or factor D deficiency have a case fatality rate of >50%, although recurrence is rare in survivors.[38,42,43]

In vitro opsonophagocytosis plays a greater role in killing capsular group B meningococci than A, C, Y, or W meningococci despite equivalent C3 binding to the surface of the capsular group B and Y organisms.[44] This finding may explain the relative resistance of complement-deficient people to capsular group B infection and their susceptibility to capsular group Y infection.

Some further data suggest that phagocytic function may be important in immunity against meningococci. Congenital impairment of binding by phagocytes of IgG2 also can predispose to invasive meningococcal disease. In one study, children with fulminant meningococcal disease were more likely than were healthy control subjects to have poor IgG2 binding by the opsonic Fc-γ receptor IIa, which is expressed by phagocytes.[45] The decreased binding results in marked reduction in phagocytosis of meningococci opsonized with IgG2, but not of those opsonized with IgG1.

During the first 2 decades of life, most people develop bactericidal antibody directed against the capsular polysaccharides and subcapsular structures such as OMP and LPS, and these antibodies are thought to mediate naturally acquired immunity.[46] Of the known surface proteins that are important in antimeningococcal immunity, PorA appears to be the dominant immunogen (with short surface exposed segments of loop 1 and 4 of the protein containing the immunogenic epitopes), but bactericidal activity mediated by these antibodies is largely strain specific.[47] Within 2 weeks of asymptomatic acquisition of a meningococcus, the titer of bactericidal antibody against the colonizing strain increases. Cross-reacting (i.e., non–strain-specific) antibodies are directed primarily against OMP and LPS antigens.

Natural immunity can develop as a result of asymptomatic colonization with meningococci or unrelated organisms bearing cross-reactive antigenic structures.[29,48] Carriage of pathogenic meningococci in early childhood is uncommon and therefore unlikely to be responsible for the induction of early natural immunity.[48] However, carriage of *N. lactamica* and of nontypable *N. meningitidis* is common and induces cross-reacting bactericidal antibodies against other strains of meningococci.[49] Enteric bacteria bear many similar surface structures that also can cross-react with meningococci. The *Escherichia coli* K1 capsular polysaccharide cross-reacts antigenically with capsular group B meningococci,[50] and *E. coli* K92 cross-reacts with capsular group C polysaccharide.[51]

The role of cell-mediated immunity in specific host responses to meningococcus is unclear. Lymphoproliferative responses to Opa, Opc, and PorA proteins of the bacterial outer membrane have been described,[52] and age-dependent differences in the cytokine response of peripheral blood mononuclear cells following infection have been observed.[53] Although age-dependent emergence of specific mucosal T-lymphocyte immunity to meningococcus has been demonstrated,[54] evidence also indicates that such responses may be relatively tolerant and therefore poorly protective in the mucosa.[55]

Epidemiology

Meningococcal disease has 2 largely distinct epidemiologic patterns: endemic and epidemic disease.

Endemic disease consists of isolated sporadic cases and occasional small clusters of cases that are associated temporally and geographically. This pattern appears to occur everywhere that disease surveillance performed, although baseline incidence rates vary markedly among different geographic areas within the approximate range 0.1 to 7 cases per 100,000 population per year.[56] In the 1990s disease rates in the United States were at approximately 1 per 100,000,[57] falling considerably since then to <0.2 per 100,000 (Centers for Disease Control and Prevention [CDC], unpublished data, 2013). The exception is in the Pacific Northwest,[58] where higher rates were reported in the late 1990s because of an increase in cases caused by hyperinvasive capsular group B strains. By contrast, during the 1990s in the British Isles, disease rates increased to >5 per 100,000, higher than in other regions of Europe,[59] largely because of a highly virulent clone bearing the capsular group C polysaccharide capsule[60] until the disease was controlled by vaccination from 1999 onward. Most cases of endemic disease occur during the winter season in temperate climates, which may reflect an association with respiratory viral infections.

Capsular group distribution varies with time and place. During the late 1990s a rising incidence of capsular group C disease in Europe and of capsular group Y in North America was reported.[61] Until recently, capsular groups B and C were the most prevalent capsular groups in most industrialized nations, but rates of group C disease fell following introduction of group C meningococcal vaccines in many countries in Europe and in Canada and Australia,[62] and group B meningococci now are the predominant cause of disease in these regions. In the US, serogroup B cases declined in the US to approximately 55 to 65 cases annually in young adults 11 through 24 years of age before the availability of capsular group B vaccines.[63,64] Capsular groups A and W previously caused only a minority of the cases of meningococcal disease in Europe and North America in recent decades, but a sharp rise in group W cases was observed in the UK from 2012.[65] By contrast, capsular group A was the most commonly isolated organism on both sides of the Atlantic during the periods after World Wars I and II and in various parts of Europe, including Finland, and in North America during the 1970s.[66] Capsular group A meningococci caused a significant amount of disease in New Zealand during the 1980s,[67] but these meningococci were replaced by high rates of group B disease from the early 1990s,[68] thus leading to a vaccine intervention program in 2005. Outbreaks of group A meningococcal disease in Russia[69] and Poland[70] highlight the proximity to western Europe of areas with high disease prevalence.

Epidemic meningococcal disease in Africa has occurred predominantly during the dry season in an east-west belt from The Gambia to Ethiopia below the Sahara desert, with cases declining at the onset of the rainy season.[71] Epidemics also have been reported in other developing countries, including China, Nepal, Mongolia, India, and Pakistan. Rates are far higher than endemic disease. For example, in a severe epidemic in Africa in 1996, attack rates of up to 1 in 100 people were recorded. The predominant capsular group is A, although epidemics of capsular groups C, W, and X have been recorded.[72–74] Epidemics of disease also have occurred in conditions of overcrowding,[75] and epidemics of groups A and W have been associated with the Hajj pilgrimage to Saudi Arabia, thus leading to a requirement for immunization before travel.[76]

Factors Influencing Disease Susceptibility and Severity

Susceptibility

Host and pathogen factors that determine susceptibility to and occurrence of meningococcal disease are summarized in Box 125.1. The most important host factor is age. The peak incidence of endemic meningococcal disease occurs in the first year of life, with 35% to 40% of cases occurring in children younger than 5 years of age.[1,57,77] A review of 807 cases of meningococcal disease occurring between 1992 and 1996 in the US found that infants <1 year of age had the highest incidence of disease, when all capsular groups were taken together.[57] The median ages for patients with disease caused by capsular groups B, C, Y, and W in this report were 6, 17, 24, and 33 years, respectively, an observation that may be important for vaccine programs designed for direct effects. Thirty percent of cases of group B meningococcal disease occurred in infants <1 year of age, compared with 14% of cases of disease caused by other capsular groups. Median age increases during epidemics.

Box 125.1

Risk Factors for Invasive Meningococcal Disease

Lack of bactericidal antibody to acquired strain

Age <1 year or 15–24 years of age

Crowded living conditions or close contact (poor housing, military barracks, students in dormitories)

Cigarette smoking, active or passive

Previous viral respiratory infection (especially influenza)

Inherited properdin or factor D deficiency

Inherited or drug-related terminal complement component deficiency (C5–C9)

Family or household contact of person with meningococcal disease

Other factors predisposing to meningococcal disease are overcrowding, poverty, cigarette smoking or exposure to cigarette smoke, previous viral respiratory tract infection, winter or dry season,[78] moving into new communities,[79,80] and certain immunodeficiencies.[81–88] In a case-control study, household smoking had an odds ratio for meningococcal disease of 4.1 (95% confidence interval [CI], 1.6 and 10.7).[82] In a study of military recruits, active or passive smoking raised the risk of carriage of *N. meningitidis*.[89] Coexistent colonization or infection with respiratory viruses and *Mycoplasma* species was associated with meningococcal disease in a study from Chad,[84] and previous studies have implicated influenza A as a predisposing factor.[85] People of low socioeconomic status also are more likely to be carriers and to develop disease.[90]

Deficiency of either antibody or complement increases the risk of meningococcal disease. Compared with the general population, inherited deficiency of properdin or of a terminal component of complement (C5–C8) increases the risk of invasive meningococcal disease by 250-fold and 600-fold, respectively,[91,92] as a result of impaired bacteriolysis even in the presence of specific antibody.[93] However, the proportion of all cases of meningococcal disease that are associated with complement deficiency is small. Patients receiving eculizumab (Soliris, Alexion Pharmaceuticals, New Haven, Conn), a monoclonal antibody used primarily for treatment of atypical hemolytic uremic syndrome, increases the risk of meningococcal disease including serogroup B.[94] Five of 326 subjects (1.5%) in clinical trials of eculizumab developed invasive meningococcal disease despite previous immunization with meningococcal conjugate vaccine.[94]

Indications for screening for complement deficiency by performance of total hemolytic complement activity assay are as follows: recurrence of meningococcal disease; chronic meningococcemia; endemic disease caused by capsular groups other than A, B, and C; and a history of a sibling with recurrent meningococcal disease. Routine screening of all patients with meningococcal disease for complement deficiencies probably is not indicated.[95]

Patients with terminal complement component deficiency should be vaccinated with the conjugated meningococcal vaccine, which reduces the risk of recurrent disease.[96] In addition, both patients and their families should be aware of patients' need for prompt medical care for acute febrile illnesses.

Studies of human single nucleotide polymorphisms have indicated various host factors that may be associated with susceptibility to invasive meningococcal infection, as reviewed by Emonts and coworkers.[20] Polymorphisms in Fc-gamma receptor II and III (CD32 and CD16) are more common in children with meningococcal disease, presumably as a result of reduced binding of IgG2 on the surface of phagocytes.[97] A multinational European study showed an excess of structural variants in mannose-binding lectin exon 1 in cases of meningococcal infection compared with controls,[98] and another study found that single nucleotide polymorphisms in factor H binding protein were associated with increased risk of disease.[99]

Seven families of genetically related *N. meningitidis* have been described (the hyperinvasive lineages) that account for a majority of the invasive infections.[8] These organisms appear to be genetically stable over time and across all geographic regions, a property indicating that they have adapted well to a particular life cycle of colonization and transmission that maintains the persistence of the clonal group. Acquisition of a hyperinvasive *N. meningitidis* increases the risk of disease.

Severity

Severity of meningococcal disease is related to host, pathogen, and other environmental factors. Large numbers of polymorphisms in human genes involved in inflammation, coagulation, and the immune response have been studied, and several associations have been reported (reviewed by Emonts and colleagues[20] and Texereau and associates[100]). Furthermore, some meningococcal clones have been associated with higher case fatality rates and more severe disease.[101]

The delivery of early and optimal medical care compared with late diagnosis and suboptimal medical care was associated with improved outcome in a study of deaths in the UK. Observations on changing case management in the UK suggest that early and rapid cardiovascular resuscitation (particularly volume replacement) may have more impact than early administration of antibiotics, at least in settings within an advanced healthcare system.[102–105]

Transmission and Colonization

Transmission of *N. meningitidis* occurs by means of respiratory droplets and requires close, direct contact. In a meta-analysis, carriage prevalence of *N. meningitidis* increased through childhood from 4.5% in infants to a peak of 23.7% in 19-year-old adults and subsequently decreased to 7.8% in 50-year-old adults.[106] Most strains recovered from carriers younger than 5 years of age are not encapsulated; carriage of encapsulated strains is uncommon until adolescence.[106,107] Capsular group B is the most frequently isolated capsular type in carriage studies from Europe (30%–40%), followed by capsular group Ys (10%–15%), C (5%–7%), W (3%–4%), and A (2%).[108,109] Studies conducted in the UK a decade after a high uptake conjugate vaccine campaign for all children and adults up to the age of 23 years in 2000 to 2001 demonstrated persistently low (although not nonexistent) rates of group C meningococcus carriage[110,111] in young people. Carriage rates of group C meningococcus also were low in the UK before immunization was begun, when group C cases were more frequent.[112]

Asymptomatic carriers are the most common sources of transmission, and evaluation of herd immune effects following introduction of group C meningococcal vaccines suggests that adolescents and young adults are the main vehicles of transmission for this capsular group in the population. Close contacts are the sources of acquisition in most individual cases. Disease is more correctly associated with acquisition than carriage because the incubation period is very short in most cases. Studies in military recruits show that illness often occurs within 48 to 72 hours of colonization.[113] During outbreaks of disease in military recruits, intense transmission occurs, so that 60% to 80% of recruits become carriers of outbreak strains within 6 to 8 weeks of starting basic training. High colonization rates have not been associated with disease outbreaks in semiclosed civilian populations, such as colleges and universities.[114,115] The highest carriage rates are detected at the beginning of the first term in the first year of higher education.[116]

When members of the households of patients with capsular group B or C disease are studied, 20% to 40% of contacts are found to carry the disease strain, and secondary cases of disease occur among close contacts at rates up to 1000 times higher than in the general population.[117]

With the introduction of group C meningococcal conjugate vaccine in the UK, which included a catch-up program in children and young adults as well as a rolling program for infants, carriage rates of groups A, B, W, and Y remained unaffected, whereas carriage rates of group C decreased from 0.45% to 0.15% in 15- to 17-year-old adolescents.[112] This study highlights the finding that colonization rates of disease-associated meningococci in the general population usually are <5%,[118,119] even during outbreaks in a college or school population.[120,121]

Few longitudinal studies have attempted to address duration of carriage. A study of group A stains in Africa suggested that the organism may persist in the nasopharynx for 3 months.[122] By contrast, the median duration of carriage of group B meningococci in another study was 9 months.[123]

Outbreaks

School-related outbreaks have been associated with capsular group B meningococci,[124] but most outbreaks have been caused by group C strains.[125–128] The first described outbreaks occurred in Canada in the late 1980s, but subsequent outbreaks related to schools, colleges, and universities have been reported from the US,[57,86] the UK,[120] Sweden,[129] Germany,[130] Spain,[131] Argentina,[132] and Australia.[133] More recent outbreaks caused by group B strains have occurred in universities in the US, thus prompting mass immunization campaigns and expedited licensure in the US of 2 meningococcal cell wall protein vaccines designed to protect against group B disease. The number of cases in each group B outbreak is small (<10), but in most outbreaks, the proportion of fatal meningococcemia among cases in 15- to 24-year-old patients is high.[86]

Risk factors for college and university outbreaks are summarized in Box 125.2. As in outbreaks among military recruits, the risk of non–group B disease is greatest in first-year college students, especially those living in dormitories.[120,134–136] Meningococcal carrier rates rise rapidly in the first few months after students arrive at college.[88] The highest carriage rates among first-year university students in the UK are during the first week of their first term.[116] These data and the higher age-specific incidence of disease in people 15 to 19 years old,[137] as well as the overrepresentation of people between 12 and 19 years of age in cases occurring in the school-related clusters in Canada and among freshman college dormitory residents in the US, suggest that adolescents transmit meningococci to one another.[86,125] Behaviors such as kissing, smoking, and prolonged duration of close contact in relatively small groups (at dances, parties, and bars, as well as in dormitories) may facilitate transmission of meningococci.[116,138,139] However, for unexplained reasons, no second adolescent peak in incidence is seen in some regions (e.g., Latin America).[140]

Box 125.2

Risk Factors Associated With Meningococcal Disease in College and University Outbreaks

Being a first-year student

Living in a dormitory

Attending a bar, nightclub, disco, or social function within 10 days before onset of the index case

Smoking

Intimate kissing

Although cases arising in college-related outbreaks account for only 3% of all cases in the US, the resulting disruption of college activities and the costs of outbreak management led the American College Health Association to recommend in 1997 that college health services alert students and parents about the risks of meningococcal disease and the benefits of vaccination. Following earlier recommendations concerning polysaccharide vaccine and following vaccine licensure in 2005, the CDC and the American Academy of Pediatrics recommended universal administration of quadrivalent conjugate meningococcal vaccine (MenACWY) to young adolescents (at 11–12 years of age), with catch-up immunization of students entering high school or 15-year-old adolescents and college freshmen who will be living in dormitories.[130] In 2010, the CDC and the AAP recommended a booster dose of MenACWY at 16 years for persons immunized at age 11 or 12 years to ensure persistence of protective levels of bactericidal antibody.[141]

Clinical Manifestations

The spectrum of clinical manifestations of infection with *N. meningitidis* ranges from asymptomatic carriage, the most common form of infection, to death within hours with fulminant meningococcal septicemia (meningococcemia). Meningococcal meningitis and septicemia are the most frequently reported clinical syndromes.

"Benign or unsuspected meningococcemia" has been observed in infants and young adults[142] with a clinical presentation of fever and signs of upper respiratory tract illness without toxicity, meningismus, or rash. Neither clinical features nor laboratory tests reliably distinguish febrile children with unsuspected meningococcemia (i.e., with fever but with no characteristic rash) from those without bacteremia.[143] Although some infants eliminate unsuspected meningococcemia without antibiotic treatment, two thirds of untreated cases progress to meningitis, fulminant meningococcemia, or other complications.[144]

Several clinical algorithms for assisting in the diagnosis and management of the child presenting with a fever and a nonblanching rash have been described,[145–149] but none has been fully, independently validated. These algorithms may enable the clinician to improve the specificity of the diagnosis, although loss of sensitivity for diagnosis of meningococcal disease could obviously have serious consequences.

The rash in all forms of meningococcal disease begins as macules, maculopapules, or urticaria but usually becomes petechial within hours. Large purpuric lesions evolve in severe cases, but some children who die of overwhelming sepsis may have no rash.

The more frequent clinical challenge is the child with fever and a petechial rash (Fig. 125.3). Only 2% to 11% of children with fever and a petechial rash have meningococcal disease; most of the remaining children have a viral illness, predominantly caused by enterovirus. Other viruses associated with petechiae include influenza and other respiratory viruses, parvovirus, Epstein-Barr virus, cytomegalovirus, and measles virus.[150–152] Petechiae or purpura also can occur with coagulation disorders such as congenital or acquired (after varicella infection) proteins S or C deficiencies.[153,154] Other disorders associated with petechial rash include platelet disorders (e.g., idiopathic thrombocytopenic purpura, drug effects, and bone marrow infiltration), Henoch-Schönlein purpura, connective tissue disorders, and trauma (including nonaccidental injury in children). The differential diagnosis of other invasive infection includes septicemia caused by pneumococci, streptococci, staphylococci, gram-negative bacilli, or rickettsia.[155,156] In the case of pneumococcal purpura fulminans, hyposplenism is an important association.

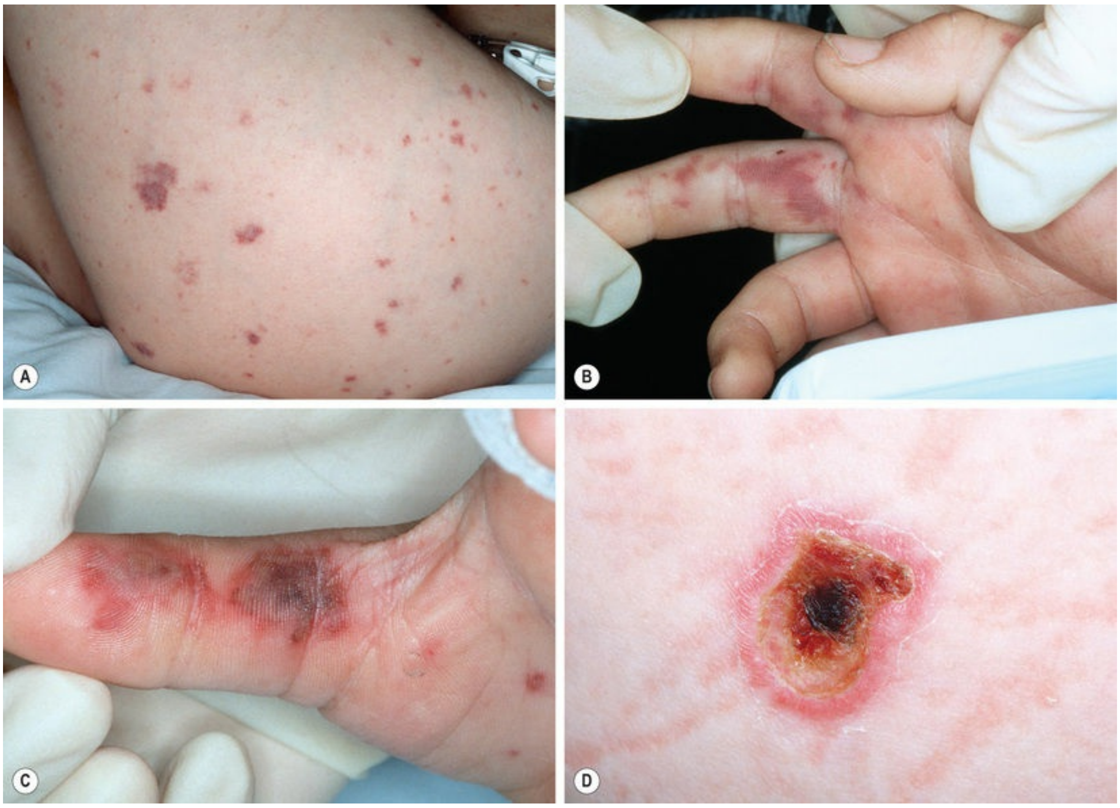

FIGURE 125.3 An 8-year-old boy had acute onset of fever, purpuric rash, and shock. *Neisseria meningitidis* was isolated from blood culture. He recovered. Typically, petechiae and purpura are most dense on (A) buttocks (day 1), lower extremities, and (B)

peripherally (day 1). (C) Tissue damage (day 4) and (D) necrosis (day 10) can ensue. (Copyright by J.H. Brien.)

Histologic analysis of skin lesions shows widespread endothelial necrosis of small veins and capillaries in the dermis and subcutaneous tissue, infiltration of neutrophils, and occlusion of damaged vessels with platelets, WBCs, fibrin thrombi, and hemorrhage.[157] Meningococci are present within the endothelium and thrombi.

Meningitis is the most common form of invasive disease and is associated with a petechial rash in two thirds of patients.[1] Headache, fever, vomiting, irritability, photophobia, lethargy, and neck stiffness can be present, and the Kernig sign can be positive in advanced cases in older children. Seizures occur in as many as 20% of cases, and mental state is altered as disease progresses. Many of the features of meningitis are not reported by younger children, and misery can be the dominant clinical feature. Infants can present with poor feeding, unconsolable irritability, a high-pitched cry, and a bulging fontanelle.

Meningococcal septicemia is a fulminant illness characterized by the onset of a nonspecific febrile illness followed within a few hours by rapid deterioration. Many deaths occur within 12 hours, and almost all occur within 48 hours, of onset. Initial symptoms include fever, headache, myalgia, shivering, cold hands and feet, and influenza-like symptoms and may be associated with vomiting and abdominal pain. Limb pain is a feature in some patients. Features of shock include tachycardia, poor peripheral perfusion, tachypnea, and oliguria. As shock progresses, cerebral perfusion decreases, resulting in alteration in mental status (confusion, agitation, or decreasing consciousness), multiorgan failure, and hypotension as a preterminal event.[126–161] The petechial rash can progress rapidly to purpura and ecchymoses.

Septicemia accounts for 15% to 20% of all cases of invasive meningococcal disease, but some patients also have a mixed picture of meningitis and septicemia. Septicemia is more common in infants and young children.[162,163] The case-fatality rate exceeds 40% in older case series, although more recent reports from specialist pediatric intensive care units in the UK showed improved survival; the mortality rate was less than 5%, with an emphasis on early correction of shock with volume replacement.[103] Many survivors lose extremities or extensive areas of skin as a result of vascular damage and peripheral ischemia and infarction.[164–166] Predictors of death and poor outcome include young age, absence of meningitis, presence of coma, absence of fever, and presence of hypotension, leukopenia, or thrombocytopenia.[167,168]

Less common manifestations of invasive disease are pneumonia, pyogenic arthritis, purulent pericarditis, myocarditis, endophthalmitis, conjunctivitis, primary peritonitis, and osteomyelitis. The incidence of meningococcal pneumonia is not known because the cause is confirmed only if blood or pleural fluid culture results are positive. Compared with patients who have meningitis or bacteremia caused by *N. meningitidis,* patients with pneumonia tend to be older (94.4% are >10 years old) and are more likely to be infected with less common capsular groups, such as W, Y, and Z.[77,169] Meningococcal conjunctivitis should be managed as invasive disease because topical therapy does not prevent invasion, and secondary cases can occur.

Chronic meningococcemia, first described in the early 1900s,[170] is a rare form of meningococcal infection, characterized by recurrent episodes of fever, rash, and arthralgia or arthritis and headache over weeks to months in association with bacteremia that often clears without treatment. The same strain usually is responsible for recurrent episodes, and the patient is well between attacks.[171,172] One study indicated that chronic meningococcemia was associated with the LpxL1 mutant strain that has a less toxic pentacylated LPS molecule.[173] Chronic meningococcemia can mimic acute rheumatic fever, bacterial endocarditis, anaphylactoid (Henoch-Schönlein) purpura, infectious mononucleosis, disseminated gonococcal infection, and immune-mediated vasculitis. The diagnosis is difficult because blood culture results are positive only if the specimen is obtained during a febrile episode. If not recognized and treated, chronic meningococcemia can progress to meningitis or acute meningococcemia. The pathogenesis of chronic meningococcemia is unknown, but inherited deficiencies of terminal components of complement have been found in some cases.[174]

Diagnosis

The diagnosis of meningococcal disease should be made clinically, and appropriate therapy should be instituted immediately. Microbiologic confirmation is important for public health control, to confirm antibiotic sensitivity, and to exclude an alternative diagnosis. Specimens from normally sterile sites (most commonly CSF) are inoculated onto chocolate agar and incubated in 3% to 5% carbon dioxide. Specimens from mucosal sites are inoculated on selective media (e.g., Thayer-Martin chocolate agar) to which vancomycin, colistin, and nystatin have been added to inhibit growth of competing microbes. Visualization of intracellular or extracellular diplococci on Gram staining of CSF, fluid from skin lesions, or the buffy coat of blood can provide positive results immediately. Scrapings or aspirates from skin lesions also can be used for diagnosis (Gram stain and inoculation onto chocolate agar).

Blood culture results may be positive in 40% to 75%, and CSF culture results are positive in 90%, of patients with meningococcal meningitis who have not received antibiotics. Some blood culture media contain sodium polyanethol sulfonate, which can inhibit *Neisseria* spp., and these organisms are very sensitive to a delay in transport to the microbiology laboratory or inoculation of CSF samples onto agar. Results of Gram stain of CSF are positive in 75% to 80% of patients with untreated cases of meningitis, and the test has a specificity of 97%. Combining results of blood and CSF cultures with those of the CSF Gram stain identifies 94% of cases of meningitis. Culture of blood, CSF, and skin lesions improves laboratory confirmation of disease. However, administration of oral or parenteral antibiotics before specimens are obtained reduces the rate of positive results of blood cultures to <10% and of CSF cultures to approximately 50% in patients who have meningitis.[163]

Detection of meningococcal antigen in CSF by latex agglutination can be useful in patients who previously received antibiotics, but the test has poor sensitivity and specificity, particularly for capsular group B, the predominant cause of the disease in most industrialized countries, and it is not recommended routinely if polymerase chain reaction (PCR) is available as an adjunct to culture.[175] PCR assays can detect meningococcal DNA in CSF, plasma, and serum.[176–178] PCR assays may use different amplification methods and gene targets[176,179]; optimal PCR systems are reported to have sensitivity and specificity of >90% and to permit diagnosis within 4 to 8 hours.[179,180] PCR is more sensitive than blood culture, and the proportion of laboratory-confirmed cases of meningococcal disease is increased by 30% to 40% when PCR is included in the investigation of suspected meningococcal disease because the assay is relatively less affected by previous antibiotic therapy.[181]

Lumbar puncture can be associated temporally with deterioration in some patients with meningococcal disease, and in patients with shock the procedure can compromise cardiovascular function.[182–184] Lumbar puncture is contraindicated in patients with cardiorespiratory insufficiency, raised intracranial pressure, coagulopathy, and extensive or spreading purpura and after convulsions until the patient's condition is stabilized. Lumbar puncture can be deferred until the patient's condition is stabilized, when abnormal CSF findings can confirm meningitis, and PCR can be used to confirm the cause.

Some patients come to medical attention in a coma, and computed tomography brain imaging may be helpful to exclude intracranial hemorrhage in patients in whom diagnosis is unclear. However, clinically significant raised intracranial pressure or cerebral edema may not be evident on computed tomography, and the decision to perform a lumbar puncture instead should be based on clinical assessment.[185,186]

Metabolic and Hematologic Abnormalities

In meningococcal meningitis, the CSF WBC count, the peripheral blood WBC count, and inflammatory markers (C-reactive protein, procalcitonin, and erythrocyte sedimentation rate) typically are elevated. Biochemical and coagulation test results usually are normal, but inappropriate antidiuretic hormone secretion can occur and lower the plasma sodium concentration. The CSF shows pleocytosis with raised protein, low glucose, and the presence of gram-negative diplococci.

In meningococcal septicemia, metabolic derangements are common and contribute to depressed myocardial function. Hypoglycemia, hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia, and metabolic acidosis are present frequently in severely affected children and should be corrected.[105,187] Renal failure, anemia, and coagulopathy also can occur, and patients may have spontaneous pulmonary, gastric, or cerebral hemorrhage, particularly in the presence of thrombocytopenia. Because onset may be very rapid, normal or depressed WBC and normal C-reactive protein values are common initially. Protein C, fibrinogen, prothrombin, coagulation factors (V, VII, and X), and antithrombin levels typically are depressed. Tissue factor pathway inhibitor is raised. Coagulopathy can be corrected with fresh frozen plasma, platelets, and, in severe cases, cryoprecipitate, to prevent life-threatening hemorrhage.

Treatment

Antimicrobial Agents

Use of a third-generation cephalosporin, such as ceftriaxone or cefotaxime, for initial therapy of suspected meningococcal disease seems prudent because meningococcal strains that are relatively resistant to penicillin appear to be susceptible to these antibiotics (discussed later) and because third-generation cephalosporins also provide coverage for *Haemophilus influenzae* and most cases of *Streptococcus pneumoniae*. In geographic locations where penicillin-resistant cephalosporin-resistant pneumococci are prevalent, addition of vancomycin is recommended.

Prehospital antibiotic therapy is recommended in some countries, especially when any delay in transfer to hospital is likely. No high-quality studies, however, address the benefit of such an approach, and available observational data are conflicting. Urgent transfer to a hospital may improve outcome among patients with septicemia because fluid resuscitation appears to be the clinical priority.

For confirmed disease, ceftriaxone (80 mg/kg/day, maximum 4 g/day, in 1–2 divided doses, intravenously), cefotaxime (200 mg/kg/day, maximum 12 g/day, in 3–4 divided doses [50 mg/kg/dose], intravenously), penicillin G (50 mg/kg every 4–6 hours, maximum 2.4 g every 4 hours), or chloramphenicol (100 mg/kg/day, maximum 2 g/day, 4 divided doses orally or intravenously) is effective.[188] Ceftriaxone sterilizes the CSF more rapidly than does cefotaxime, ampicillin, or chloramphenicol ($P < 0.01$), although the clinical importance is unknown.[189] Many countries recommend penicillin for confirmed disease in view of its low cost and narrow spectrum, although penicillin, unlike the third-generation cephalosporins, does not clear nasopharyngeal colonization. Chloramphenicol is widely used and effective in resource-poor settings, and it is used elsewhere in patients with severe β-lactam allergy. One randomized controlled trial in Turkey found that necrotic skin lesions occurred more frequently with penicillin G therapy than with ceftriaxone ($P < 0.05$).[190] In the UK, ceftriaxone is recommended as definitive therapy for penicillin-susceptible organisms because it appears to be less expensive when administration costs are considered, and the long half-life and dose interval also make it easier for children who can complete treatment as outpatients.[36]

Emergence of strains with increased resistance to penicillin (i.e., with a minimum inhibitory concentration between 0.12 and 1.0 µg/mL) has been reported from Africa, the UK, Spain, Argentina, the US, and Canada.[191] Failure of penicillin therapy for meningitis caused by such strains is reported, but these strains remain susceptible to third-generation cephalosporins.[192] Resistance results from a genetic mutation that appears to have been acquired from avirulent *N. lactamica* or other *Neisseria* spp. through DNA transformation and causes alteration in penicillin-binding protein 2. The highest prevalence of penicillin resistance has been reported from Spain, where rates exceed 40%.[193] Although the frequency of penicillin-resistant *N. meningitidis* has increased in many parts of the world, the prevalence in the US remained unchanged at 3% between 1991 and 1997,[194] and it remained unreported in the Netherlands in 2012.[195]

Although the recommended duration of therapy for meningitis and meningococcemia is 7 days, no high-quality studies are available to support any specific duration of therapy. In some studies, treatment with penicillin, chloramphenicol, or ceftriaxone for 4 to 5 days appeared to be effective. Treatment with 1 or 2 doses of ceftriaxone or a long-acting oily suspension of chloramphenicol, in a developing country, was shown to be as effective as more prolonged therapy.[196–203]

The appropriate duration of therapy for meningococcal infections at other sites (bone, joint, heart, lung) has not been established, although descriptive evidence supports short-course treatment of arthritis[204]; nevertheless, patients with such infections should be treated at least until all clinical and laboratory signs of infection have resolved.

Adjunctive Therapy

The use of corticosteroid therapy for presumed meningococcal meningitis is controversial because no pediatric studies have had an adequate sample size to assess benefit, although benefit has been shown for other bacterial causes of meningitis.[205] Studies in developing countries do not show benefit from corticosteroid therapy in bacterial meningitis.[206] However, studies in adults in industrialized countries have shown benefit in all-cause meningitis and a trend toward benefit in meningococcal meningitis.[207] If used, dexamethasone can be administered in a dose of 0.15 mg/kg 4 times daily for 4 days.

No studies of high-dose corticosteroid treatment in children with meningococcemia or other types of shock have been conducted, but data from adult studies showed no benefit and the potential for harm. Studies of low (“physiologic”) doses in adults showed conflicting results, but some authorities believe that replacement doses (25 mg/m^2 hydrocortisone 4 times daily) may be useful in children who have refractory shock in association with impaired adrenal gland responsiveness; investigation in Europe is ongoing.[208,209]

Reduced concentrations of protein C have been found in the plasma of patients with meningococcal sepsis, and low levels are associated with an increased risk of death. Activated protein C inhibits both inflammatory and procoagulant pathways that are activated by the proinflammatory cytokines released in response to sepsis and reduces mortality rates in adults with sepsis.[210] Although small controlled trials showed increased survival in treated patients,[211–213] a randomized, placebo-controlled study of the use of activated protein C in children with severe sepsis failed to demonstrate apparent benefit in children with septic shock, and serious bleeding was a complication.[214] Protein C is therefore not recommended.

Recombinant bactericidal permeability-increasing protein (rBPI), which binds to endotoxin and blocks the inflammatory cascade, was studied in a randomized, multicenter, placebo-controlled trial, but the study was not sufficiently powered to assess a reduction in mortality rates adequately.[215,216] However, children who received rBPI had fewer amputations, decreased blood product transfusions, and improved functional outcome, and fewer children died who received a full 24-hour infusion of rBPI (2% rBPI vs. 6% placebo; P = 0.07).

Various other agents and other adjunctive therapies have been used or considered in the management of septicemia including fibrinolysis, extracorporeal membrane oxygenation, plasmapheresis, and antimediator therapy, but only the antiendotoxin antibody, HA1A, has been subjected to rigorous clinical trials and did not show benefit.[217] None of these adjunctive therapies currently are recommended.

Emergency Management

Pulmonary edema or poor pulmonary perfusion and hypoxia can be present in patients with meningococcal septicemia and requires elective endotracheal intubation during volume resuscitation. Intubation also is recommended if the patient is still in shock after 40 to 60 mL/kg of volume resuscitation because pulmonary edema is common during ongoing resuscitation. After securing the airway, the 2 clinical management priorities in children with meningococcal disease are correction of cardiovascular shock and control of raised intracranial pressure. Most patients die of decompensated shock, and a few die of raised intracranial pressure. Aggressive volume resuscitation and inotropic support to maintain tissue perfusion are critical to improving survival and minimizing sequelae in patients with fulminant disease and shock. Children with meningococcal septicemia may require fluid replacement volumes equivalent to or several times greater than their circulating blood volume. Fluid replacement should be administered initially as 0.9% sodium chloride solution in a volume of 20 mL/kg over 5 to 10 minutes and repeated until shock improves (reduction in heart rate and increased tissue perfusion). Human albumin solution (4.5%) is recommended as an alternative by many intensivists, but currently no data are available to guide the type of fluid to be used. If the child is still in shock after receiving 40 to 60 mL/kg of fluid, vasoactive therapy is required. Metabolic derangements, anemia, and coagulopathy should be monitored and corrected as appropriate. Renal support may be necessary. For the child with raised intracranial pressure, management should be directed at ensuring adequate cerebral perfusion by correcting coexistent shock and by providing neurointensive care. In patients with meningococcal meningitis without raised intracranial pressure or inappropriate secretion of antidiuretic hormone, volume resuscitation should be aggressive. No evidence supports the historical practice of fluid restriction in such cases, and one study found increased rates of neurologic sequelae among patients who had fluid restriction.[218] Analysis of the mechanisms of excess 48-hour mortality rates reported in children with severe febrile illnesses who were given fluid boluses in a randomized trial in Africa[219] indicates that death was not primarily caused by respiratory or neurologic events associated with fluid overload but by cardiovascular collapse.[220] Accordingly, fluid resuscitation and inotropic support remain the standard approaches to meningococcal shock in settings where close observation and intensive support are available.

An algorithm has been developed to assist direction of early management in both children and adults,[106,221] and updated versions are available from the Meningitis Research Foundation website (www.meningitis.org).

Outcome

Mortality

The overall case-fatality rate for invasive meningococcal disease is approximately 10%.[57,179,222,223] In a case series from the Netherlands,[224] the risk of death was higher in infants <6 months of age, adolescents, and adults >50 years of age (odds ratio, 5.1, 3.4, and 9.8, respectively) than in children 1 to 9 years old. The risk of death was greater among female patients (odds ratio, 2.3; 95% CI, 1.2 and 4.7).

Death or severe ischemic damage with extremity loss or extensive skin gangrene occurs much more commonly in fulminant meningococcemia than in meningitis. Optimized initial management and aggressive supportive care in the pediatric intensive care unit of the most severely affected patients have been associated with a reduction in mortality rates in this group of patients from a predicted risk of death of 25% to less than 5%.[136] With prompt and appropriate antibiotic and supportive therapy, patients with uncomplicated cases of meningococcal disease improve rapidly. Most patients with meningitis return to a normal state of consciousness within 2 days, are afebrile within 3 to 4 days, and show resolution of meningismus within 4 to 5 days.

Prognostic scoring systems have been developed that use presenting clinical signs and laboratory findings.[225–227] The first of these systems demonstrated that the combination of 3 or more of the following features was associated with a poor prognosis: (1) petechiae for less than 12 hours before presentation, (2) hypotension, (3) absence of meningismus, and (4) peripheral blood WBC lower than 10,000 cells/mm^3 and an erythrocyte sedimentation rate less than 10 mm/hr.[228] The Glasgow meningococcal septicemia prognostic score[229] has been widely used as a research tool but tends to overestimate mortality. The clinical utility of scoring systems has not been fully established.

Postinfectious Inflammatory Syndromes

Various immunologic or reactive complications, such as arthritis, cutaneous vasculitis, iritis, and pericarditis, can occur in patients with meningococcal disease from 4 days after the onset of invasive disease (after bacteriologic eradication). The mechanism is focal deposition of immune complexes containing meningococcal polysaccharide antigen, IgG, and C3 that results in acute inflammation.[230] All forms of reactive disease resolve spontaneously. Symptoms usually can be relieved by administration of acetylsalicylic acid or nonsteroidal anti-inflammatory agents.

The rate of reactive arthritis is 5% to 8%; reactive arthritis more often is reported in adults than in children, and it affects medium-sized joints preferentially.[231] Fever occurs at the time of onset of joint pain, and arthritis resolves within 6 to 10 days without residual damage. The onset of arthritis is associated with the disappearance of meningococcal antigen from the serum, a rise in antibody titer, and a drop in serum C3 concentration.[232]

Cutaneous vasculitis occurs in approximately 2% of patients, with onset 5 to 9 days after appearance of disease.[213] Small numbers of warm, red papules appear, mainly on the extremities, and they often progress to form bullae that rupture, leaving a shallow ulcer. Several crops of papules can appear over 2 to 3 days. Healing occurs without scarring in 4 to 8 days.

Inflammation of the iris or sclera occurs in approximately 1% of patients, often in association with reactive arthritis or vasculitis.[231] Reactive pericarditis, characterized by chest pain, pericardial friction rub, recurrence of fever, and sterile, nonpurulent pericardial exudate, also can occur.[233] Concurrent presence of polyarthritis and polyserositis is common. Pericardial effusion rarely leads to tamponade or requires drainage.

Sequelae

Rates of severe and moderate neurologic sequelae after 5 years are lower after meningitis caused by *N. meningitidis* (2.9% and 6.5%, respectively) than following meningitis caused by *H. influenzae* (3.4% and 7.3%, respectively) or *S. pneumoniae* (9.7% and 13.9%, respectively).[234] In 562 cases of meningococcal disease in the Netherlands, 8.5% of survivors had one or more sequelae, including deafness in 3.1%, motor dysfunction in 1.2%, and other neurologic deficits in 1.2%.[225] The frequency of sequelae did not vary significantly with the serogroup or serotype of the pathogen or with the sex or age of the patient. A review of 471 cases of invasive meningococcal disease in Quebec, Canada, between 1990 and 1994 demonstrated significantly higher rates of death (13.8% vs. 7.2%) and major complications such as skin scars and amputations (15.3% vs. 3.2%) in patients infected with group C than in those with group B meningococcal infection, respectively.[222]

Psychological problems are frequently reported, and neurologic deficits are found in 7% of patients.[36] It is important to perform follow-up auditory testing in all patients with meningococcal disease to identify hearing loss (rate of occurrence 2% to 15% of cases in various studies),[235] as well as to provide hearing aids and plan cochlear implantation as necessary in a timely manner.

Perfusion of the skin and muscle can be severely compromised in meningococcal shock, and areas affected by purpura and pressure areas can be necrotic and at risk of secondary infection. In one study, ischemic infarction of skin and soft tissues resulted in significant scarring or extremity loss in 3.9% of survivors, most often after fulminant meningococcemia.[225] Multiple areas are involved in most patients. The limbs are the predominant sites of damage. In a study of 21 patients with skin infarction, the lower limbs were involved in 20, the arms in 9, the trunk in 8, the face in 4, and the scalp and ear in 1 each.[236] The mean area of skin necrosis was 13% of total body surface area. Across several studies, skin damage or scarring was noted in 13% of cases.[36]

Limb compartment syndromes often are observed during the course of disease, and fasciotomy has been used in management in some circumstances, but its role is not established clearly.[237] Except in the presence of infection, amputations of ischemic limbs should be undertaken late to allow maximum limb recovery before lines of viability are finalized. Amputations are necessary in approximately 3% of cases, and a further 3% of patients have other orthopedic complications. With effective surgical treatment, rehabilitation, and support such patients can achieve a high quality of life; clinicians therefore should not be deterred from active management in the acute phase of the disease.[238]

Impaired organ perfusion results from hypovolemia, vasoconstriction, and myocardial depression resulting in prerenal failure in some patients, with oliguria or anuria or acute tubular necrosis. Most patients recover without any renal support, some require hemofiltration, and rarely permanent renal failure ensures.

Prevention

Management of Contacts

Household and kissing contacts of a patient with meningococcal disease are at significantly increased risk of meningococcal disease

(Box 125.3).[86,239,240] The incidence of disease in household contacts, although still low, is 500 to 1000 times that in the general population.[241] In sporadic cases of disease, 1% to 3% of households have 1 or more secondary cases of disease within 30 days of onset of the index case if no intervention occurs.[242] Approximately 20% of secondary cases are coprimary infections (i.e., occurring on the same day as the index case); 30% of secondary cases occur in the first week, 20% in the second week, and 30% in weeks 3 to 8 after the index case. Because of the rapid onset in 50% of related cases, early antibiotic prophylaxis when indicated, education, and close follow-up of contacts to ensure rapid intervention if they experience febrile illness are important. Culture of specimens from contacts usefully does not inform management.

Box 125.3

Contacts of a Patient With Meningococcal Disease Who Are at Increased Risk of Disease

Household members

Childcare center and nursery school contacts

School or college contacts during outbreak

Anyone directly exposed to a patient's oral secretions through mouth kissing or the sharing of food, drinks, utensils, glasses, water bottles, or anything that has been in the mouth of the patient

Healthcare personnel exposed directly to the patient's oral secretions through mouth-to-mouth resuscitation, or endotracheal intubation or tube management in the first 2 days of therapy without wearing a surgical mask[a]

---

[a] Healthcare workers without such exposure are not at increased risk.

Adapted from Advisory Committee on Immunization Practices. Prevention and control of meningococcal disease: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Morb Mortal Wkly Rep 2000;49:1; and Pollard A, Begg N. Meningococcal disease and healthcare workers. BMJ 1999;319:1147.

Trials of mass prophylaxis with sulfadiazine in military recruit camps during World War II suggested efficacy for eradication of carriage and interruption of epidemics. However, mass prophylaxis has not been effective in other situations,[243] and usually it is avoided. The emergence of worldwide resistance of capsular groups A, B, and C to sulfonamide drugs after 1963 led to the investigation of other agents for use in eradication of meningococcal carriage as a means of prophylaxis. Efficacy against all capsular groups has been noted for rifampin, minocycline, ceftriaxone, ciprofloxacin, and ofloxacin. Minocycline rarely is used for prophylaxis because of its high rate of adverse effects (dizziness, nausea, and vomiting).

Rifampin is the only agent that has been studied widely, but it has the following disadvantages: (1) the eradication rate is only 80% to 85%; (2) adverse effects occur in 25% of patients; (3) 4 doses are required; (4) rifampin is expensive and not readily available; and (5) a liquid suspension is not always available for children.[241] Moreover, emergence of resistance to rifampin can occur rapidly. Ceftriaxone, administered as a single intramuscular injection, has been shown to be >97% effective in eradicating carriage.[244] Additional advantages are single-dose therapy and safety during pregnancy. Disadvantages are the pain associated with intramuscular injection and potential adverse effects on mucosal flora related to broad-spectrum activity. Ciprofloxacin and ofloxacin effectively eradicate meningococcal carriage after a single oral dose.[245–248] However, fluoroquinolones are not approved for use in pregnant women, and the use of these drugs is restricted in children in some countries.

All contacts must be treated immediately and concurrently for maximal impact on secondary cases. Otherwise, untreated carriers could infect contacts who have already completed prophylaxis. Treatment of patients with index cases with ceftriaxone also eradicates carriage. Patients who are treated with antibiotics not known to eradicate carriage should receive appropriate prophylaxis before hospital discharge to prevent reintroduction of the pathogen into the household or community.

Details of prophylactic regimens are given in Table 125.2. Prophylaxis is not routinely recommended for the following: (1) school, church, or community contacts; or (2) medical personnel caring for the patient, except for those who have unusual, direct exposure to respiratory secretions through mouth-to-mouth resuscitation, or intubation or suctioning without wearing a mask.[249] Prophylaxis is recommended for infants and young children who have been in close contact with affected people in daycare centers.

TABLE 125.2

Chemoprophylaxis Regimens for Contacts of Patients of Meningococcal Disease

Antibiotic	Dose
Rifampin	10 mg/kg per dose (maximum dose 600 mg) PO every 12 hours for 4 doses (for infants <1 month of age, 5 mg/kg per dose)
Ceftriaxone	Single injection of 125 mg for <15 years and 250 mg for ≥15 years[a]
Ciprofloxacin	20 mg/kg (max 500 mg) >1 month of age[a]

Immunization

Polysaccharide Vaccines

Vaccines composed of purified capsular polysaccharide of large molecular size have been developed against capsular groups A, C, W, and Y and have been formulated as monovalent A and C, bivalent A/C, and quadrivalent A,C,W,Y vaccines (PsACWY). The major vaccine-related determinants of immunogenicity are the molecular size and dose of the vaccine, and the major host factor is age.[250,251] Currently licensed vaccines contain 50 µg of each capsular group polysaccharide per dose. Vaccines are safe, with rare reports of serious systemic events.[251–254] Benign febrile seizures have been reported rarely in young children who have undergone vaccination with bivalent group A and group C vaccine.[255] Transient local reactions, such as erythema and tenderness, can occur at the site of injection. These reactions are more common after quadrivalent vaccine (30% to 40%) than after monovalent group A or C vaccines (8% to 10%).

In US adults vaccinated with PsACWY, bactericidal antibodies directed at group A and C polysaccharides peaked at 1 month, declined after 2 years, but remained higher than baseline for 10 years after vaccination.[256] In rural Nigeria, however, increases in antibody to group A polysaccharide were not sustained 2 years after vaccination.[257]

Protection induced by meningococcal vaccine is capsular group specific. Group A vaccine is effective in preventing disease in all age groups (Box 125.4). Two doses administered 2 to 3 months apart in infants 3 to 18 months of age (or 1 dose in older children and adults) have a protective efficacy >95%.[66,67] Group A vaccine appears to be effective in terminating epidemics of group A disease, although logistical challenges limit the impact of this approach. However, because duration of protection against invasive disease in adults does not appear to last more than 3 to 5 years, PsA vaccine is not recommended for routine use.

Box 125.4

Recommended Uses of Meningococcal Vaccines

Recommended Uses

Routine immunization of infants or toddlers with monovalent capsular group C meningococcal conjugate vaccine (MenC) recommended in some countries (currently not available in the United States) with booster doses increasingly advised in adolescence to maintain individual protection and herd immunity

Routine immunization of children at 11 or 12 years of age and with catch-up immunization of those through 18 years of age, using a quadrivalent conjugate capsular group ACYW vaccine (MenACYW), recommended in the US. Booster doses of MenACYW for adolescents advised in some countries with established MenC programs in early childhood.

Routine immunization of infants with MenB vaccine recommended in the United Kingdom (2-, 4-, and 12-month schedule) and some subcountry regions of Europe and Canada (2-, 4-, 6-, and 12-month schedule) (2 MenB are licensed currently in the US)

Immunization of at-risk populations for control of outbreaks caused by capsular groups contained in vaccine

Immunization with relevant meningococcal vaccines of travelers to an epidemic area (see Table 125.3 for US recommendations)

Routine immunization in high-risk setting with MenACWY or MenB vaccines, or both (see Table 125.3 for US recommendations)

Immunization of children with special high-risk conditions:

- UK recommendations: **Persistent complement deficiencies** at 9 months of age and children with **other high-risk conditions such as asplenia** at 2 years of age, with MenACWY in a 2-dose series 3 months apart. MenB vaccine also advised for these populations in some countries

- US recommendations: **Persistent complement deficiencies, functional or anatomic asplenia, HIV infection, or risk during a community outbreak attributable to vaccine serogroup** (beginning at 2 months of age for HibMenCY-TT [MenHibRix, GlaxoSmithKline, Philadelphia, Pa] or MenACWY-CRM [GlaxoSmithKline]; beginning at 9 months after primary pneumococcal conjugate vaccines for MenACWY-D [Menactra, Sanofi Pasteur, Swiftwater, Pa])

- **Travel to or residence in country where meningococcal disease is hyperendemic or epidemic** (beginning at 2 months of age for MenACWY-CRM and 9 months of age for MenACWY-D) (see Table 125.3 for US MenB recommendations)

Revaccination

Routine booster immunization of adolescents at 16 years of age who received MenACYW at 11 or 12 years of age or at 18 years of age for those who received MenACYW at 13 or 14 years of age. No booster recommended routinely for persons who received MenACYW at ≥15 years of age

Booster immunization of persons in high-risk groups every 5 years (with first booster after 3 years in those immunized at <2 years of age who continue to be at high risk of disease)

Recommendations for boosters of MenB vaccine pending

Contraindications

Severe reaction (anaphylaxis) to previous dose of vaccine

Immunization with the PsC vaccine has been >90% effective in preventing disease in young adults, and its routine use in the military eliminated outbreaks of group C disease.[258,259] However, PsC vaccine is poorly immunogenic in infants. Repeated doses of group C vaccine, unlike group A vaccine, do not cause an anamnestic response at any age. Indeed, 1 dose of PsC vaccine was shown to induce immunologic hyporesponsiveness to subsequent doses in infants, toddlers, and adults.[251,260–262] The duration and clinical relevance of such hyporesponsiveness are uncertain, but the phenomenon can last several years in recipients.[249,263]

Group Y and group W polysaccharide vaccines are immunogenic in children older than 12 to 24 months of age. Proof of efficacy has not been obtained, mainly because of the absence of epidemics caused by groups W or Y until more recent W outbreaks.[65,264,265]

The polysaccharide vaccines largely have been superseded by the glycoconjugate vaccines.

Conjugate Vaccines

Conjugation of group A, C, W, and Y polysaccharides to proteins such as CRM197 (CRM), tetanus toxoid (TT), or diphtheria toxoid (D) achieves similar or greater immunogenicity and duration of protection in infants, children, adolescents, and adults without increases in reactogenicity, compared with the much larger doses in plain polysaccharide vaccines.[260–268] Moreover, the conjugated vaccines induce immunologic memory,[261,263] unlike polysaccharide vaccines, and can overcome the hyporesponsiveness induced by previous doses of some polysaccharide vaccines.[262,269] Conjugated group C vaccines also have been shown to induce salivary IgG and IgA antibodies in infants vaccinated at 2, 3, and 4 months of age,[270] adolescents,[271] and young adults,[272] and general use of the vaccine is associated with reduction in carriage rates.[112]

Because of a significant rise in the incidence of group C disease, a mass immunization program was started in November 1999 in the UK with meningococcal conjugate C (MenC) vaccines from 3 manufacturers.[273] Vaccination was offered first to infants <1 year of age and adolescents 15 to 17 years of age, the age groups at highest risk. Subsequently, vaccine was offered to all children and young adults <24 years of age. The campaign was highly effective both as a result of direct protection of individual people and perhaps more as a result of community (herd) protection through reduction in transmission of the organism.[112,274,275]

MenC vaccines have been licensed and used in many other countries on the basis of the efficacy demonstrated in the UK, by using either a 2- or 3-dose infant schedule or a single-dose toddler schedule with a catch-up campaign.[62,276] Data from the UK show that persistence of antibody after primary infant immunization is poor, and effectiveness data indicate that protection wanes to 0 by 1 year after completion of the 3-dose infant schedule.[274] In response to this finding, the UK Department of Health announced the addition of a booster dose of MenC vaccine in 2006 to be administered in the second year of life. However, more recent studies suggest that persistence of functional antibody is poor even after this booster dose given at 1 year of age.[277] By contrast, persistence of antibody is more sustained after primary immunization of children who are older than 10 years of age.[278] Furthermore, a marked response to a booster and persistence of antibody occur for at least 1 year if the booster is administered beyond 6 years of age.[279] Booster doses in adolescents now have been implemented or are being considered in several countries with an infant MenC program. Vaccination of this age group appears likely to interrupt transmission of MenC bacteria, and thus introduction of boosters should maintain the community protection induced following the mass campaigns at the time of vaccine introduction. In a study of 53 people who developed invasive group C meningococcal disease despite receipt of MenC vaccine, antibody response to disease was consistent with an anamnestic response, a finding indicating that persistence of antibody may be a better correlate of long-term protection than priming for immune memory.[280]

In 2005, MenACYW-D (Menactra, Sanofi Pasteur, Swiftwater, PA) was licensed and recommended for universal use in the US in children at the age of 11 years.[139] Preliminary data from the CDC in 2010 indicated a vaccine effectiveness of 75% (95% CI, 17 to 93).[281] Cases of Guillain-Barré syndrome (GBS) occurring within 6 weeks of receipt were reported soon after implementation of MenACYW-D for adolescents. Ongoing investigations since then in the US, as well as surveillance in Canada, describe no excess cases or rare excess cases over that predicted, and most experts no longer consider GBS to be a risk of the vaccine.[282,283] MenACYW-CRM (GSK vaccines, Rixsensart, Belgium) was launched in 2010 in Europe and North America, and MenACYW-TT (Pfizer Vaccines, Pearl River, NY) is also available in some regions. In view of their immunologic advantages, the MenACYW conjugate vaccines should replace the plain polysaccharide vaccines for all indications in children and adults. MenACYW vaccines are recommended universally at 11 years and from 2 months of age for those at increased risk of meningococcal disease.[141]

Waning of bactericidal antibody following MenACWY immunization given at 11 or 12 years of age led to the US recommendation in 2010 for a second dose at 16 years of age, or at 18 years of age if the primary dose was given at 13 through 15 years of age.[141] In countries with established monovalent C conjugate vaccination programs in early childhood the quadrivalent MenACWY vaccine or the monovalent MenC vaccine is being introduced to overcome waning population immunity among adolescents, as described earlier. The former approach has the advantage of maintaining control of capsular group C disease and protecting the vaccinated teenagers from A, Y, and W infection while also inducing community protection to prevent disease caused by all 4 groups across ages.

Prospects for control of epidemic group A meningococcal disease in the meningitis belt of Africa have been enhanced by an alliance between the World Health Organization (WHO) and the Program for Appropriate Technology in Health (PATH) to develop a monovalent capsular group A meningococcal vaccine for Africa, funded by the Bill & Melinda Gates Foundation. Vaccine program implementation began across the meningitis belt of Africa during 2010, and results indicate a decline in disease among vaccinated populations.[284]

Development of a polysaccharide vaccine against group B meningococci, the major cause of endemic disease, is thwarted by the relative lack of immunogenicity of the B polysaccharide in humans.[285] Because B polysaccharide has structural and immunologic identity with sugars decorating the neural cell adhesion molecule, a membrane glycoprotein on human neurons in the developing brain, such antibodies have the potential to be autoreactive and thus harmful.[286] Field trials of a vaccine containing outer membrane vesicles (OMVs) (blebs of bacterial outer membrane containing OMPs, lipid, and LPS) derived from a Norwegian outbreak strain reduced the incidence of group B disease among schoolchildren aged 14 to 16 years by 53%.[287] A Cuban OMV vaccine from a local outbreak strain may have had somewhat greater efficacy in Cuba,[288] but it did not perform so well when tested in other settings against heterologous strains. OMV vaccines may have limited utility for endemic disease because the bactericidal antibody elicited appears to be limited largely to the immunodominant strain-specific PorA proteins. However, this property makes OMV vaccine ideal for control of an outbreak caused by a single clone, such as in New Zealand, in which a single group B clone caused a prolonged epidemic starting in the early 1990s. An OMV vaccine based on the outbreak strain was first used in 2004 with high apparent effectiveness,[289] and the program was discontinued in 2008. Since the vaccine campaign, most cases caused by the outbreak strain have been among unvaccinated people, a finding suggesting that the vaccine may still be providing some protection in the population.[290]

Development of a more comprehensive capsular group B vaccine has been an important public health goal, and many vaccine candidates have been considered over the past 3 decades, as reviewed by Sadarangani and Pollard.[291] Data from the genome-sequencing projects have provided information about novel vaccine candidates,[14] and 2 vaccines have been licensed by various regulatory authorities: a 4-component vaccine containing meningococcal factor H binding protein, neisserial adhesion A, neisserial heparin binding antigen, and the New Zealand outbreak strain OMV (MenB-4C); and a 2-component vaccine containing 2 variants of meningococcal factor H binding protein (2fHbp) (MenB-FHbp). Data from studies of these vaccines in adults and children indicate that the vaccines induce bactericidal antibody against strains bearing the antigens contained in the vaccine and provide in vitro evidence of potential cross-protection to other endemic strains of meningococci that contain and express variants of the vaccine antigens.[292–296] MenB-4C has been developed both for infants and adolescents (as with other meningococcal vaccines) and has waning of antibody after vaccination in early childhood, although this characteristic is variable among the vaccine components,[297–300] and persistence of immunity is better among adolescents. Some evidence indicated an impact of MenB-4C vaccine on carriage of the organism in the oropharynx in a study of university students, but uncertainty remains about whether this effect is sufficient to induce community protection.[110] MenB-4C (GSK) was introduced into the UK infant immunization program for all infants at 2, 4, and 12 months of age in September 2015, and it has been used for university and community outbreaks of disease in the US and Canada, respectively. Early data from the UK program indicate vaccine effectiveness (VE) of 82.9% (95%, CI 24.1–95.2) against all capsular group B disease in infants, which is presumed to be an underestimate of true VE since the vaccine is not expected to cover all circulating strains. Two group B meningococcal vaccines (MenB-FHbp [Trumenba, Pfizer, New York, NY] for a 3-dose series and MenB-4C [Bexsero, GlaxoSmithKline] for a 2-dose series) were licensed by the US Food and Drug Administration by an accelerated pathway in 2014 and 2015 for children and adults 10 through 25 years of age. The AAP and the CDC recommend use of MenB vaccine for high-risk groups (Table 125.3). The current low number of *N. meningitidis* B cases in the US makes universal recommendation of MenB vaccines cost prohibitive. Despite outbreaks of group B on US college campuses, the incidence of disease in college students (0.09 per 100,000) is similar to or lower than the incidence in all 18 through 23 year olds (0.14 per 100,000) (CDC, unpublished data), thus precluding a recommendation of MenB vaccine for college students alone.[94] Approval was based on clinical trial immunogenicity data rather than clinical efficacy.

TABLE 125.3

Increased Risk Groups Recommended for the Different Meningococcal Vaccine

MenACWY	MenB
Complement deficiency[a]	Complement deficiency[a]
Anatomic or functional asplenia[b]	Anatomic or functional asplenia[b]
HIV infection	
Outbreak caused by MenACWY[c]	Outbreak caused by MenB[c]
Microbiologists[d]	Microbiologists[d]
Travelers[e]	—
First-year college students[f]	—
Military recruits	—

[a] Inherited or chronic deficiencies of C3, C5-9, properdin, factor D, or factor H or eculizumab (Soliris) use.

[b] Includes sickle cell disease.

[c] The Centers for Disease Control and Prevention defines outbreaks and those at risk: http://www.cdc.gov/meningococcal/downloads/interim-guidance.pdf.

[d] Only microbiologists who routinely work with *Neisseria meningitidis.*

[e] To areas with hyperendemic or epidemic meningococcal disease.

[f] Unvaccinated or inadequately vaccinated first-year college students who live in residence halls.

MenACWY, quadrivalent meningococcal A, C, Y, W conjugate vaccine; MenB, meningococcal B vaccine.

Key Points

Diagnosis, Management, and Prevention of *Neisseria meningitidis* Infection

Microbiology

- Catalase-positive, oxidase-positive, piliated Gram-negative coccus that oxidizes glucose and maltose

- Outer phospholipid membrane contains endotoxin and various outer membrane proteins that are subject to phase variation.

- Can be surrounded by a polysaccharide capsule or acapsulate; 5 capsule “capsular groups” associated with most global disease: A, B, C, Y, and W

- Grows well on chocolate or blood agar; enhanced growth in humidified carbon dioxide environment

Epidemiology

- Highest rate of colonization (up to 40%) in adolescents and young adults; colonization rare in children <10 years of age

- Respiratory route of transmission

- Peak of disease in children <2 years of age and smaller peak in adolescence

- Risk of disease increased by smoking (active and passive), overcrowding, previous viral respiratory tract infection, winter or dry season, moving into new communities, complement deficiency, and various human single nucleotide polymorphisms.

- Capsular group distribution varies over time and with geographic location: B and C (where vaccine has not been introduced) account for most disease in Europe; B, C, and Y in North America; and capsular group A in Africa and Asia.

- In developed countries most cases are sporadic but small clusters can occur (mostly capsular group C strains). Epidemics of disease can occur (mainly capsular group A, with some X or W) in developing countries, especially the meningitis belt of Africa.

Clinical Features

- Four presentations, all of which are most often associated with a nonblanching (petechial or purpuric) rash:

- Meningitis with a mortality rate <5%
- Septic shock (meningococcemia or meningococcal septicemia) with a high mortality rate
- A mixed picture of meningitis and shock
- Bloodstream infection without shock or meningitis

- Death usually is caused by cardiovascular collapse in patients with septic shock or, rarely, by raised intracranial pressure in patients with meningitis.
- Complications include the following: a self-limiting inflammatory reactive syndrome; neurologic sequelae (including deafness). following meningitis; and limb, digit, and skin scarring or loss after septic shock

Diagnosis

- Microbiologic diagnosis usually is made by Gram stain of CSF or culture of blood (automated culture system) or CSF
- PCR of blood or CSF can yield higher rate of identification (especially with receipt of antibiotic before sampling)

Treatment

- Ceftriaxone is recommended as empiric therapy for suspected cases
- Urgent management of shock includes volume replacement therapy and supportive care (mechanical ventilation and inotropic drugs)
- Meningococcal meningitis should be managed with antibiotics and maintenance fluids with careful assessment for coexistent shock or raised intracranial pressure

Duration of Therapy

- Duration of therapy should be 5 to 7 days, but some studies suggest that as little as 1 dose of an appropriate antibiotic may be sufficient

- Response to therapy usually is rapid

Vaccine Prevention

- Monovalent capsular group C meningococcal conjugate vaccines (MenC) are widely used in Europe, Australia, and Canada for routine immunization of infants or toddlers and are highly effective, although more recent data suggest that an adolescent booster is required to maintain population immunity

- Quadrivalent meningococcal A, C, Y, W conjugate vaccines (MenACYW) are used routinely in North America for adolescent immunization and are now recommended in many countries for high-risk groups and travelers (as young as 2 months of age) and are being adopted to replace MenC as an adolescent booster outside the US

- Booster doses of MenACYW are recommended in the US for high-risk children and persons immunized at <15 years of age

- Capsular group B outer membrane vesicle (OMV) vaccines have been used successfully for outbreaks involving single clones but are not suitable for endemic, polyclonal disease

- Two novel capsular group B vaccines (MenB-4C, 2-dose series; MenB-FHbp, 3-dose series) aimed at broad capsular group B coverage have been licensed for people ≥10 years of age. Recommendations in the US are limited to at-risk patients and outbreak settings, and the vaccines can be given at 16 through 23 years of age at “clinical discretion”

CSF, cerebrospinal fluid; PCR, polymerase chain reaction.

Neisseria gonorrhoeae

Katherine K. Hsu, Zoon Wangu

Neisseria gonorrhoeae is a pathogen only of humans. Gonorrhea, one of the oldest known human illnesses, continues to result in significant morbidity; an estimated 106 million cases occur worldwide each year.[1] In the United States, gonorrhea is the second most frequently reported communicable disease after *Chlamydia trachomatis*.[2] The reader is referred to organism- or syndrome-specific chapters for the overall approach to genital tract infections. The major public health impact of the sexually transmitted infection (STI) gonorrhea is acute salpingitis, which is one of the leading causes of infertility in women around the world. Gonorrhea also is a potent amplifier of the spread of human immunodeficiency virus (HIV), by increasing rates of HIV sexual transmission up to fivefold.[3]

Microbiology, Virulence, Immunity, and Pathogenesis

N. gonorrhoeae, an oxidase-positive, gram-negative diplococcus, primarily infects columnar or transitional epithelial cells in the human genital tract. Transmission results almost exclusively from intimate contact, such as sexual activity or parturition. Adherence to mucosal epithelium is mediated by numerous gonococcal surface structures, including pili, opacity-associated outer membrane (Opa) proteins, and lipo-oligosaccharides (LOSs), and is followed by penetration of organisms between and through epithelial cells to submucosal tissue.[4] Cytokine release, which usually occurs in the process of invasion of male urethral cells, contributes to the symptomatic nature of gonococcal disease in men.[5] A neutrophil response follows, with subsequent sloughing of the epithelium, pus formation, and development of submucosal microabscesses. If infection is untreated, macrophages and lymphocytes eventually replace neutrophils, and hematogenous extension can occur. In contrast, subversion of host immune function can occur in women with uncomplicated cervical infection, resulting in a lack of antibody and interleukin production.[5] However, in a model of upper genital disease that uses organ explant culture of fallopian tubes, gonococcal endotoxin (lipopolysaccharide) impairs ciliary motility and contributes to the destruction of surrounding ciliated cells.[6]

N. gonorrhoeae has evolved multiple mechanisms to evade host immune responses, with resulting successful adaptation to variable microenvironments (e.g., the male urogenital tract, the female lower and upper genital tracts that also vary throughout the menstrual cycle, and the human bloodstream).[5] Although both humoral and local secretory antibodies to *N. gonorrhoeae* are induced during some uncomplicated infections, specific antibodies are rendered ineffective by antigenic variation of gonococcal surface molecules.[7] For example, the organism can perform the following functions: (1) turn on or off the synthesis or shift the expression of pili, Opa proteins, and LOS; (2) vary surface immunoaccessibility of porin (Por) and LOS antigens; (3) elicit antibody responses that are not protective (e.g., antibodies to the reduction-modifiable protein [Rmp] that block bactericidal activity of other antibodies against Por and LOS); and (4) alter LOS enzymatically by sialylation, thereby causing a loss of serum bactericidal activity.[8] The organism also resists clearance by neutrophil oxidative and nonoxidative killing mechanisms.[9] The exact role of host defense mechanisms in modulating infection or conferring immunity to reinfection is unclear because repeated infections are common.

Epidemiology

Approximately 820,000 new *N. gonorrhoeae* infections occur annually in the US.[10] In 2014, 350,062 US cases were reported; the incidence of reported disease rose from 98 cases per 100,000 population in 2009 (a historic low) to 111 cases per 100,000 population in 2014.[2] During 2010 to 2014, the rate among men increased 28%, whereas the rate among women decreased 4%. The magnitude of increase among men compared with the decrease among women suggests either increased transmission or increased case ascertainment (e.g., through increased extragenital screening) among gay, bisexual, and other men who have sex with men (collectively referred to as MSM). However, most jurisdictions do not routinely report the sex of the patient's sex partner or the site of infection for gonorrhea cases, so trends in gonorrhea rates among MSM over time cannot be assessed.[2] The highest incidence overall is among women and men 20 to 24 years of age (Fig. 126.1).[2] When data are examined by single-year age groups, in California, rates of infection are much higher in women 18 and 19 years of age than in women 15, 16, or 17 years of age; these findings indicate the potential for more targeted prevention and treatment efforts in settings serving older adolescents and young adults.[11] Prevalence continues to be highest in girls and women, in the 14- to 19-year-old age group, in non-Hispanic blacks, and in the residents of inner cities.[12,13] The risk of gonorrhea in adolescents and young adults is multifactorial, including an increased likelihood of multiple sex partners, unprotected sex, and susceptibility to infection as a result of cervical ectopy (in adolescent women), as well as less access to STI prevention services (lack of insurance or other ability to pay, lack of transportation, discomfort with facilities designed for adults, and concerns about confidentiality).[2,14] Additional risk factors include older sexual partners and substance abuse, particularly of alcohol and marijuana.[15,16]

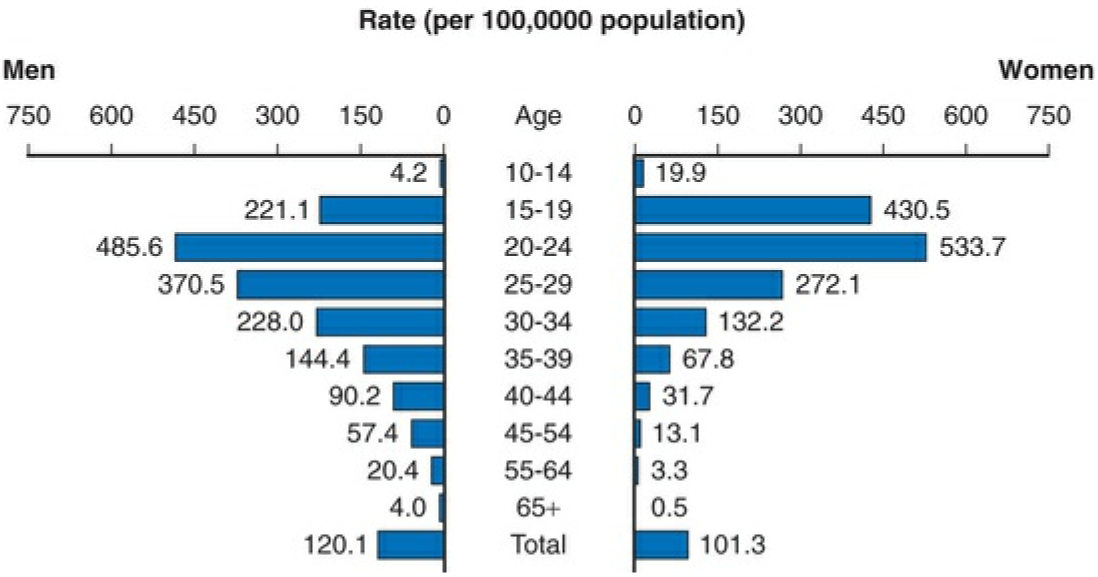

FIGURE 126.1 **Age- and sex-specific rates for gonorrhea, United States, 2014.** (From Centers for Disease Control and Prevention. Sexually Transmitted Disease Surveillance. Atlanta, GA, United States Department of Health and Human Services, 2015.)

The likelihood of transmission of *N. gonorrhoeae* depends on the anatomic site exposed and the number of exposures. A man's risk of acquiring urethral infection after a single episode of vaginal intercourse with an infected woman is approximately 20%; the risk increases to 60% to 80% after 4 exposures.[17–19] The risk of male-to-female transmission has not been evaluated as thoroughly but is probably ~50% to 70% after a single contact, with little evidence that risk increases with multiple exposures.[19,20] The risk of transmission by rectal or oral contact is less well defined but is thought to be relatively efficient for insertive or receptive rectal intercourse. Pharyngeal gonorrhea can be acquired easily through fellatio, which may account for 26% of cases of urethral gonorrhea in MSM.[19] Oral sex is a highly prevalent practice among heterosexual young people, regardless of whether they have engaged in penetrative intercourse. As a result, pharyngeal gonorrhea has become increasingly prevalent, particularly among adolescents. In 2 Los Angeles STI clinics, 65% of patients between 15 and 24 years of age reported having oral sex; in this group, the prevalence of pharyngeal gonorrhea was 6% compared with 7% for urogenital gonorrhea.[21]

Prevalence in a community is sustained through continued transmission by asymptomatically infected people and also by a “core group” of transmitters who are more likely than the general population to become infected and to transmit *N. gonorrhoeae* to their sex partners.[22] Characteristics of core groups include demography (e.g., low socioeconomic status, geographic clustering in inner cities) and unique behavior (e.g., history of repeated gonococcal infections, drug use, multiple sex partners, prostitution, and failure to abstain from sex despite symptoms or knowledge of recent exposure).[23–26] Effective control efforts for gonorrhea must target both asymptomatically infected people and infected core group members.

Antibiotic Resistance

N. gonorrhoeae is facile at developing resistance to commonly used antimicrobial agents. The epidemiology, genetics, and mechanisms of resistance have been described.[19,27] Risk factors for antibiotic resistance include travel outside the community, high-risk behaviors, and recent antibiotic use, but these risk factors are not always identified in patients infected with resistant *N. gonorrhoeae*.[23–26,28,29]

The history of recommended antimicrobial therapy and development of resistance is well known. The organism has evolved to resist each single agent used formerly as first-line therapy. The emergence of cephalosporin resistance and the accompanying cephalosporin treatment failures worldwide[30–32] (though not yet in the US), prompted designation of *N. gonorrhoeae* as antibiotic resistance threat level "Urgent" by the US Centers for Disease Control and Prevention (CDC) because of the potential clinical impact, economic impact, incidence, 10-year projection of incidence, transmissibility, availability of effective antibiotics, and barriers to prevention.[33] The percentage of isolates with elevated cefixime mean inhibitory concentrations (MICs; ≥0.25 μg/mL) has varied between 0.8% and 1.4% in recent years of surveillance in the US Gonococcal Isolate Surveillance Project; elevated ceftriaxone mean MICs (≥0.125 μg/mL) have occurred in 0.1% to 0.4% of isolates, but no treatment failures have yet been identified in the US.[2] Although most definitions of cephalosporin resistance are based on ceftriaxone, important differences in susceptibility can exist across cephalosporins, thus precluding generalizability of cephalosporin susceptibility monikers. Resistance mechanisms include altered penicillin binding proteins, reduction of antimicrobial entry into cells, and active efflux. β-Lactamase has not been found in strains of *N. gonorrhoeae* that express relative cephalosporin resistance. Currently the only reliable method for detecting resistance to cephalosporins consists of isolation and susceptibility testing. Limitations of direct specimen testing using nucleic acid amplification tests (NAATs) are incomplete correlations among identification of specific mutations, MICs, and clinical outcomes.[27]

Clinical Manifestations

N. gonorrhoeae typically infects susceptible columnar or transitional epithelial cells (e.g., mucous membranes of the conjunctiva, pharynx, urethra, endocervix, and rectum). Infection often remains localized to the site of inoculation but can disseminate.

Perinatal Infections

Perinatal infection generally is acquired during passage through an infected birth canal, although transmission can occur after cesarean delivery, especially following premature rupture of membranes. Infant risks for infection include lack of appropriate ophthalmic prophylaxis, lack of maternal prenatal care, and maternal history of STI or substance abuse. An infant born to a woman with cervical gonococcal infection has an approximately 30% risk of acquiring ophthalmic infection,[34] versus a <5% risk if ocular prophylaxis is given.[35]

Ophthalmia Neonatorum

The usual incubation period for gonococcal ophthalmia neonatorum is 2 to 5 days, but onset can be as early as several hours after birth (following prolonged rupture of membranes) or as late as several weeks.[36] Prematurity and premature rupture of membranes are significant risk factors for gonococcal ophthalmia. The time of onset and clinical findings do not reliably distinguish *N. gonorrhoeae* conjunctivitis from *C. trachomatis* conjunctivitis.

Typical findings of gonococcal conjunctivitis are marked bilateral eyelid edema, chemosis, and copious purulent discharge. Asymptomatic infection or mild chronic infection with intermittent symptoms lasting for several months also has been reported.[37] Although gonococcal conjunctivitis generally is less severe in neonates than in adults, corneal complications, such as ulceration and perforation of the globe (rarely), panophthalmitis, and blindness, can occur.[38]

Other Perinatal Infections Including Systemic Infection

N. gonorrhoeae can be isolated from culture of pharyngeal swabs or orogastric fluid in approximately one third of infants with ophthalmia neonatorum.[39,40] Examples of neonatal mucosal infections include vaginitis (uncommon because neonatal vaginal mucosa is well estrogenized by circulating maternal hormone), urethritis, rhinitis, anorectal infection, and funisitis. *N. gonorrhoeae* scalp abscess can follow fetal electrode monitoring.[41,42]

Disseminated disease is rare in neonates; pyogenic arthritis is the most common manifestation.[43,44] Clinical symptoms typically develop at 1 to 4 weeks of age; pseudoparalysis is characteristic. Multiple joint involvement is common.[43] Most affected infants do not have concurrent or previous conjunctivitis or other mucosal infections. Skin lesions representing septic emboli of bloodstream infection (BSI), commonly seen in adults, are not described in neonates. Rarely, neonatal infection results in meningitis[45] or endocarditis.

Mucosal Infections in Children, Adolescents, and Adults

N. gonorrhoeae causes a variety of mucosal infections in sexually active adolescents and adults, as well as in sexually abused children. Transmission by fomites or through nonsexual contact is extremely rare.

In prepubertal children, gonococcal infection usually occurs in the genital tract, and vaginitis is the most common manifestation (the nonestrogenized alkaline vaginal mucosa permits colonization). *N. gonorrhoeae* infection should be considered in any girl with vaginal discharge, even when sexual abuse is not suspected. In a study of 43 girls <12 years of age with vaginal discharge, 9% had gonorrhea.[46] Sexual abuse must be considered strongly when gonococcal infection is diagnosed in prepubertal children (beyond the newborn period).[47] Among sexually abused children, pharyngeal and anorectal gonococcal infections are common and are often asymptomatic.[47,48] Gonococcal urethritis, perihepatitis, and pelvic inflammatory disease (PID) are uncommon but possible in prepubertal children.

Most men who come to medical attention with *N. gonorrhoeae* infection are symptomatic; asymptomatic or minimally symptomatic infections may be more common than appreciated but usually are recognized only through screening programs or after symptomatic infection in a contact.[49] In a cohort of men whose time of acquisition of the infection was defined, only 2.5% remained asymptomatic for 2 weeks.[19] However, certain phenotypes of gonococci have been more frequently associated with asymptomatic infection.[50] Acute urethritis is the major clinical manifestation in men, who complain of dysuria or note a mucoid or mucopurulent discharge 2 to 5 days after infection. The discharge often becomes profuse and purulent within 24 to 48 hours of onset.

Women are more likely than men to have asymptomatic infection or mild, sometimes unappreciated, symptoms. The endocervical canal is the predominant site of urogenital infection; urethral colonization also occurs in most cases in which the cervix is involved. The incubation period for urogenital infections in women is less certain and more variable, but in most symptomatic women, the symptoms develop within 10 days of infection.[51,52] Symptomatic female patients can have vaginal discharge, dysuria, abdominal pain, and intermenstrual bleeding; symptoms and signs range from mild to severe. The cervix can appear normal or can exhibit edema, erythema, or friability, as well as purulent or mucopurulent discharge.[53]

Pharyngeal infection occurs in approximately 3% to 7% of *N. gonorrhoeae* infections in heterosexual men and in approximately 10% to 20% of infections in heterosexual women or MSM.[54–56] Most pharyngeal infections are asymptomatic; rarely, acute tonsillopharyngitis or cervical lymphadenopathy occurs.[54,55]Pharyngeal infections can progress to disseminated gonococcal infection (DGI) if untreated.[57–60] Oral sex also has a role in sustaining gonorrhea in a population of MSM by providing a pool of untreated asymptomatic infections,[61] and it may account for as much as 34% of the population attributable risk for symptomatic gonococcal urethritis in MSM.[62]

Asymptomatic rectal infection is present in 26% to 68% of women with gonococcal cervicitis; translocation of infected secretions is thought to be the mechanism because rectal infection positivity correlates with duration of infection.[63,64] In MSM, rectal mucosa can become infected after receptive anal intercourse.[63] In contrast to MSM who experience a high proportion of rectal-only *N. gonorrhoeae* infections (≤86%), the rectum is the sole site of infection in a minority of women (≤44%).[65] Anorectal infection often is asymptomatic. If present, symptoms range from painless mucopurulent discharge and scant rectal bleeding to overt proctitis with associated rectal pain and tenesmus.[63,64]

Gonococcal conjunctivitis is rare in adults, usually results from autoinoculation, and occurs most often in people with anogenital infection. Untreated gonococcal conjunctivitis can progress rapidly to ulcerative keratitis and corneal perforation; however, mild or asymptomatic conjunctival infection also occurs. The outcome correlates closely with the severity of disease at the initiation of therapy.[66] Gonococcal conjunctivitis also has been described in prepubertal children without laboratory evidence or a suggestive history of sexual abuse.[67]

Disseminated Gonococcal Infection

Disseminated gonococcal infection (DGI), also known as the arthritis-dermatitis syndrome, is the most common manifestation of acute systemic gonococcal infection beyond the neonatal period. In the 1970s when gonococcal strains with a propensity to disseminate were common, DGI occurred in up to 3% of people with untreated mucosal gonorrhea[68–70]; DGI is much less common currently. DGI was described more commonly in women, with an onset within 7 days of the start of menstruation in approximately one half of cases[68–70]; however, more recent case series describe more male than female cases.[71,72] Certain strains of *N. gonorrhoeae* (uncommon in the US currently) are associated with disseminated infection. DGI strains often cause asymptomatic urogenital infection and typically, although not always, are penicillin G susceptible and resistant to the complement-mediated bactericidal activity of human serum.[69,70] Complement deficiency, which predisposes to gonococcal or meningococcal BSI, is found in up to 13% of patients with DGI.[73,74]

The characteristic findings of acute arthritis, tenosynovitis, and dermatitis, alone or in combination, result from intermittent BSI. Less than one half of patients with DGI have *N. gonorrhoeae* isolated from blood, joint fluid, skin lesions, or other sterile sites, but *N. gonorrhoeae* can be isolated from a mucosal site or from a sex partner in approximately 80% of cases.[68–70,75] Dermatitis occurs in approximately 75% of patients with DGI. The classic skin lesions are discrete, tender necrotic pustules on erythematous bases located distally on an upper extremity; macules, papules, petechiae, bullae, or ecchymoses also have been described. Results of culture or Gram stain of lesions are positive for *N. gonorrhoeae* in only approximately 10% to 15% of cases. Migratory polyarthralgia or tenosynovitis (especially in the flexor and extensor tendon sheaths) affecting smaller joints is an early finding. Pyogenic monoarticular or polyarticular arthritis develops later in approximately one third of patients; the wrist, metacarpophalangeal, ankle, and knee joints are involved most commonly.[68,69,70,75]

Gonococcal endocarditis is a rare complication, occurring in approximately 1% to 3% of patients with DGI.[68,69,76] The aortic valve is affected most often; valvular damage can progress rapidly if the disease is untreated. Hepatitis and meningitis are uncommon complications of DGI.

Laboratory Findings and Diagnosis

Laboratory confirmation of *N. gonorrhoeae* infection is essential in children because of the legal implications of potential sexual abuse. Confirmation also is critical in adolescents and adults to improve adherence to therapy and referral of sex partners.

Gram Stain

Gram-stained smears of exudate from the conjunctivae, endocervix of postpubertal girls and women, vagina of prepubertal girls, male urethra, skin lesions, synovial fluid, and cerebrospinal fluid can be useful, if results are positive, in the initial evaluation of patients with suspected gonococcal infection. Visualization of intracellular gram-negative diplococci (most often as multiple, kidney bean–

shaped diplococci within a relatively few neutrophils in the specimen) is presumptive evidence of *N. gonorrhoeae* infection; identifying only extracellular organisms is less specific in mucosal specimens. Compared with culture, Gram stain is 90% to 95% sensitive in urethral specimens from men with symptomatic urethritis but only 50% to 70% sensitive in endocervical specimens from women with uncomplicated gonorrhea.[19,77–79] Gram stain of pharyngeal or rectal specimens is not recommended because of a lack of specificity.

Culture

Isolation of *N. gonorrhoeae* by culture is critical to monitoring development of resistance to current antimicrobial treatment regimens.[80] *N. gonorrhoeae* does not tolerate drying; clinical specimens should be inoculated immediately onto appropriate culture media and incubated at 35°C to 37°C in an atmosphere of high humidity and 4% to 6% carbon dioxide. "Bedside" inoculation in a nutritive transport system (e.g., a polystyrene dish containing selective gonococcal media and an inner well containing a carbon dioxide–generating tablet) is helpful. *N. gonorrhoeae* grows well only on chocolate agar or similarly enriched media; media used for specimens from the urogenital tract or pharynx should contain antimicrobial agents (e.g., vancomycin, colistin, plus an antifungal agent) to inhibit growth of saprophytic organisms. Thayer-Martin and Martin-Lewis are the most commonly used enriched antimicrobial media. Sterile body fluids (e.g., blood, synovial fluid, cerebrospinal fluid) should be inoculated onto antibiotic-free, enriched media such as chocolate agar.

N. gonorrhoeae are oxidase-positive, gram-negative diplococci that use glucose but not maltose, sucrose, fructose, or lactose. *N. gonorrhoeae* can be distinguished from other *Neisseria* spp. and from *Moraxella catarrhalis* by carbohydrate use or by a nucleic acid confirmation test. Although specimens from urogenital infections generally give straightforward results, confirmation at a reference laboratory occasionally is necessary. Presumptive identification of *N. gonorrhoeae* from extragenital mucosal sites such as the pharynx should be interpreted with caution because of the expected presence of nonpathogenic *Neisseria* species; at least 2 confirmatory bacteriologic tests using different methodologies (e.g., biochemical and enzyme substrate) should be performed.[81,82]

The sensitivity of a single, properly obtained specimen inoculated onto selective media is >95% for male patients with symptomatic urethritis and 80% to 90% for women with endocervical infections. Obtaining a second endocervical specimen improves culture sensitivity in women.

Advantages of culture include low cost and availability of an isolate for further studies (e.g., antibiotic susceptibility testing or subtyping). Disadvantages include transport and growth requirements and a time delay of 24 to 72 hours from specimen collection to presumptive result.[80]

Nonculture Tests

The sensitivity of NAATs for the detection of *N. gonorrhoeae* at genital and nongenital anatomic sites is superior to culture but varies by NAAT and specimen type.[80] Product information inserts for each NAAT test must be read carefully because specimen types approved by the Food and Drug Administration (FDA) vary by test. NAATs are not FDA approved for use on specimens from the rectum, pharynx, conjunctiva, joint fluid, blood, or cerebrospinal fluid. Despite the lack of FDA approval, and to facilitate clinical management, many commercial and public health laboratories have established performance specifications to satisfy Centers for Medicare and Medicaid Services (CMS) regulations for FDA Clinical Laboratory Improvement Amendment (CLIA) compliance in testing and reporting results for nongenital specimens. Specificity is the key factor for performance because of cross-reaction with nongonococcal *Neisseria* spp. Advantages of NAATs include rapid turnaround time, flexibility in sampling source, and utility when transport problems preclude the use of culture.[80,83]

Use of NAATs performed on urine or other easily obtained genital specimens offers several advantages for detection of reproductive tract infection. Advantages include patients' preference (compared with speculum examinations of women and urethral swabs of men), the option of self-collection, and the feasibility of testing in settings where traditional genitourinary examinations are not performed, such as schools. For men, urine is the preferred sample for testing or screening because testing specimen of urine is more sensitive than urethral swab and has equivalent specificity.[80] However, NAATs can be less sensitive in women when the tests are performed on urine compared with genital (vaginal or endocervical) swab samples.[80] For women, vaginal swab samples are preferable to endocervical swabs for screening for *N. gonorrhoeae* by NAATs because of convenience and equivalent sensitivity and specificity. Endocervical swabs are acceptable when pelvic examinations are performed, but vaginal swab specimens are an appropriate sample type even when a full pelvic examination is being performed.[80]

For detection of rectal and pharyngeal infections, NAATs are superior to culture.[83–85] However, not all commercially available NAATs are equivalently specific (particularly polymerase chain reaction tests) for pharyngeal specimens or FDA approved, and results must be interpreted cautiously (see earlier).[80,83,84]

Data on the use of NAATs are limited in children, and performance depends on both sample site and the specific test. In a multicenter study of testing using strand displacement amplification or transcription-mediated amplification in children being evaluated for sexual abuse, sufficient data were collected from prepubertal girls to conclude that testing of urine samples using these 2 commercially available NAATs is a reliable alternative to vaginal culture for detection of *N. gonorrhoeae*.[86] However, culture still remains the recommended method for detection of *N. gonorrhoeae* in urethral specimens from boys and for extragenital specimens (conjunctiva, pharynx and rectum) from all children because NAATs have not yet been sufficiently evaluated for these populations and sample sites.[80]

Because accurate diagnosis is the goal, no justification exists for the routine use of less sensitive nonamplified test technologies such as nucleic acid genetic transformation, enzyme immunoassays, or nucleic acid hybridization probe assays.[80] Serologic assays for diagnosis or screening for gonococcal infection are neither recommended nor available.

Treatment

Management Considerations

The goals of antibiotic therapy are to relieve symptoms, reduce the risk of sequelae, eradicate infection, and halt transmission. Persons with suspected gonococcal infections should be treated empirically, before susceptibility test results of the isolate are known. Selection of an appropriate regimen requires consideration of local and national resistance patterns, anatomic sites of infection, likelihood of concurrent infections with *C. trachomatis* or another STI, side effects, and relative cost. Generally, ceftriaxone is the drug of choice for all gonococcal infections in the US, with dosing dependent on age and weight, and length of therapy varying by site and severity of infection (Table 126.1). On the theoretical basis that combination antimicrobial therapy using 2 agents with different mechanisms of action may enhance treatment efficacy and potentially slow the emergence and spread of resistance to cephalosporins, dual treatment with ceftriaxone combined with azithromycin is now recommended; this approach has added benefit for patients coinfected with *C. trachomatis*.[87] Further support for azithromycin as opposed to doxycycline as the second drug comes from the higher prevalence of tetracycline resistance (a proxy marker for doxycycline resistance) and the convenience and compliance of single-dose therapy. All persons diagnosed with gonorrhea also should be tested for *Chlamydia* infection, syphilis, HIV infection, and other STIs.[38]

TABLE 126.1

Recommended Treatment of Gonococcal Infections

Age Group	Infection	Treatment Regimen	Length of Therapy
Neonates	Ophthalmia neonatorum	Ceftriaxone[a] 25–50 mg/kg IV or IM once (max 250 mg) plus lavage of infected eye frequently until discharge eliminated	Once
	Disseminated infection Scalp abscess Septic arthritis	Ceftriaxone 25–50 mg/kg IV or IM every day *OR* Cefotaxime 25–50 mg/kg IV or IM q8–12h[b]	7 days
	Meningitis	Ceftriaxone 25–50 mg/kg IV or IM every day *OR* Cefotaxime 25–50 mg/kg IV or IM q8–12h	10–14 days
	Endocarditis	Ceftriaxone 25–50 mg/kg IV or IM every day *OR*	Minimum 28 days

		Cefotaxime 25–50 mg/kg IV or IM q8–12h	
Children ≤45 kg	Pharyngeal infection Anorectal infection Urogenital infection	Ceftriaxone 25–50 mg/kg IV or IM once (max 250 mg)	Once
	Conjunctivitis	Ceftriaxone 50 mg/kg IM once (max 1 g) plus lavage infected eye with saline solution	Once
	Disseminated infection Septic arthritis	Ceftriaxone 50 mg/kg IV or IM every day (max 1 g daily)	7 days
	Meningitis	Ceftriaxone 50 mg/kg IV or IM q12–24h (max 4 g daily)	10–14 days
	Endocarditis	Ceftriaxone 50 mg/kg IV or IM q12–24h (max 4 g daily)	Minimum 28 days
Adults, adolescents, and children >45 kg	Pharyngeal infection Anorectal infection Urogenital infection	Ceftriaxone 250 mg IM once *PLUS* Azithromycin 1 g PO once	Once
	Conjunctivitis	Ceftriaxone 1 g IM once *PLUS* Azithromycin 1 g PO once plus lavage infected eye with saline solution	Once
	Disseminated infection Septic arthritis	Ceftriaxone 1 g IV or IM every day	7 days
		PLUS	
		Azithromycin 1 g PO once	Once
	Meningitis	Ceftriaxone 1–2 g IV q12–24h	10–14 days
		PLUS	
		Azithromycin 1 g PO once	Once
	Endocarditis	Ceftriaxone 1–2 g IV q12–24h	Minimum 28 days
		PLUS	
		Azithromycin 1 g PO once	Once

[a] Cefotaxime should be substituted for ceftriaxone in neonates with hyperbilirubinemia (particularly neonates who are premature) and in infants <28 days of age if receiving calcium-containing intravenous fluids. Consult neonatal dosing references.

[b] Dose or dosing frequency change after postnatal age >7 days of life: consult neonatal dosing references.

IM, intramuscularly; IV, intravenously; max, maximum; PO, orally.

Return visits for test-of-cure cultures are not recommended for patients with uncomplicated urogenital gonorrhea who become or remain asymptomatic following treatment with a recommended or alternative regimen. However, anyone with pharyngeal gonorrhea who is treated with an alternative regimen should return 14 days after treatment for a test of cure using either culture or NAAT. If the

NAAT result is positive, effort should be made to perform a confirmatory culture before retreatment, with antimicrobial susceptibility testing of isolates.[88]

If symptoms persist after therapy, culture for *N. gonorrhoeae* should be obtained, and antimicrobial susceptibility testing should be performed. Symptoms of persistent urethritis, cervicitis, or proctitis also can be caused by *C. trachomatis, Mycoplasma hominis, Ureaplasma urealyticum,* and other organisms. Gonococcal infection detected after an appropriate course of therapy usually represents reinfection rather than treatment failure. Because infection occurs most commonly in patients who have been diagnosed and treated for gonorrhea in the preceding several months, patients with gonorrhea should be retested 3 months after treatment or whenever they seek medical care within the following 12 months.[38]

Gonorrhea is a reportable disease, and partner notification for evaluation and treatment is imperative to prevent reinfection of the index case patient, to eradicate large numbers of asymptomatic infections, and to interrupt transmission of the disease. In heterosexual adolescents and adults, expedited partner therapy (detailed later) should be considered.

Perinatal Infections

Infants born to mothers who have untreated gonorrhea are at high risk for infection and should be given a single dose of ceftriaxone intravenously (IV) or intramuscularly (IM), even in the absence of signs or symptoms.[38] Neither ocular silver nitrate nor topical antibiotic ointment (e.g., erythromycin, tetracycline) is adequate therapy for established gonococcal ophthalmia.[36] Infants with gonococcal ophthalmia should be hospitalized and disseminated infection should be excluded[82]; considering the rarity of gonococcal meningitis, most experts would not perform lumbar puncture in a well-appearing, afebrile infant.

Infants with uncomplicated ophthalmia neonatorum should be treated with ceftriaxone; additional topical therapy is unnecessary, but frequent saline irrigations are important.[82] Some physicians elect to continue ceftriaxone once daily until blood, joint, and cerebrospinal fluid (if obtained) culture results are negative at 48 to 72 hours. Ceftriaxone should be administered cautiously to infants with hyperbilirubinemia, especially preterm infants; cefotaxime is an alternative in these cases.[82] If DGI or gonococcal scalp infection is identified, ceftriaxone IM or IV daily or cefotaxime twice daily should be administered for 7 days. If meningitis is documented, the treatment course should be 10 to 14 days. No data are available regarding dual therapy for neonatal infection.[38,39]

The mother of an infant diagnosed with a gonococcal infection (and her sex partner) also should receive appropriate evaluation and treatment, and the infant should be evaluated for *Chlamydia* infection, syphilis, and HIV infection.

Mucosal Infections in Adolescents and Adults

Single-dose ceftriaxone 250 mg IM cures >99% of uncomplicated anorectal and urogenital infections and 99% of pharyngeal infections. Gonococci are eradicated from the urine, urethra, and semen of symptomatic men within 24 hours of therapy.[89] Azithromycin 1 g given orally in a single dose, as mentioned earlier, should be administered simultaneously with ceftriaxone for dual therapy for gonococcal infection, preferably under direct observation.

Gonococcal conjunctivitis should be treated with a single dose of ceftriaxone 1 g IM in combination with azithromycin 1 g orally; lavage with saline solution (once) should be considered.[38]

Alternative Regimens

If ceftriaxone is not available, alternative cephalosporins for uncomplicated anorectal and urogenital infection include oral cefixime or other single-dose injectable regimens (ceftizoxime 500 mg IM, cefoxitin 2 g IM administered with probenecid 1 g orally, or cefotaxime 500 mg IM). Although oral therapy avoids the cost and inconvenience of injections and decreases the risk of accidental needlestick injuries to medical personnel who may be treating a population at high risk of HIV infection,[89] the recommended 400 mg oral dose of cefixime does not provide as high or as sustained a bactericidal level as that provided by the ceftriaxone 250 mg IM. In published clinical trials, cefixime 400 mg orally cured 98% of uncomplicated anorectal and urogenital infections, but only 92% of pharyngeal infections.

As part of dual therapy, doxycycline should be given instead of azithromycin *only* if a contraindication to azithromycin (e.g., known immunoglobulin E–mediated allergy) exists, considering that gonococcal strains in the US with elevated MICs to cefixime are also likely to be tetracycline resistant but not macrolide resistant.[38]

A clinical trial of dual treatment of uncomplicated urogenital gonorrhea demonstrated that single doses of oral gemifloxacin 320 mg plus oral azithromycin 2 g were associated with cure rates of >99%, and dual treatment with single doses of intramuscular gentamicin 240 mg plus oral azithromycin 2 g cured 100% of cases. This trial was not powered to provide reliable estimates of the efficacy of these regimens for treatment of rectal or pharyngeal infection, but both regimens cured the few extragenital infections among study participants. Either of these regimens could be considered as alternative treatment options in the presence of cephalosporin allergy. However, gastrointestinal adverse events can limit their use: approximately 8% of patients treated with gemifloxacin plus azithromycin and 3% of patients treated with gentamicin plus azithromycin vomited within 1 hour of medication administration, thus necessitating retreatment with ceftriaxone and azithromycin.[90]

None of the other injectable cephalosporins offers any advantage over ceftriaxone for urogenital infection, and efficacy for pharyngeal infection is less certain. Other oral cephalosporins are similarly not recommended because of inferior efficacy and less favorable pharmacodynamics. Although cefpodoxime 400 mg orally, cefpodoxime proxetil 200 mg orally, and cefuroxime axetil 1 g orally all meet minimum efficacy criteria for alternative regimens for urogenital infections, efficacy in treating pharyngeal infections is unsatisfactory (estimated to be 70%, 79%, and 57%, respectively), and concerns exist about the pharmacodynamics of both the lower dose of cefpodoxime and the 1-g dose of cefuroxime axetil.[38]

Spectinomycin in a single 2-g dose IM may possibly be useful in persons who cannot tolerate cephalosporins (estimated efficacy 98% for uncomplicated urogenital and anorectal infections), but the drug is relatively expensive, must be injected, is not effective against pharyngeal gonococcal infection (estimated efficacy 52%) or incubating syphilis, and is not available currently in the US.[38,91,92]

Monotherapy with azithromycin 2 g orally as a single dose has been demonstrated to be 99% effective against uncomplicated urogenital gonorrhea.[93] However, monotherapy is no longer recommended because of concerns over the ease with which *N. gonorrhoeae* can develop resistance to macrolides and because several studies documented azithromycin treatment failures. The high rate of gastrointestinal symptoms associated with the 2-g dose also limits its usefulness. Azithromycin 1 g orally, the dose used for gonorrhea dual therapy, is not an appropriate alternative for monotherapy of gonococcal infection.[88]

Disseminated Infection Including Meningitis and Endocarditis in Adolescents and Adults

Hospitalization usually is recommended for initial therapy of DGI to establish the correct diagnosis and especially when purulent synovitis or another major complication is present. Azithromycin 1 g by mouth should be given as a single dose, and daily parenteral ceftriaxone should be administered until at least 24 to 48 hours after clinical improvement begins. Alternative agents include cefotaxime 1 g IV every 8 hours or ceftizoxime 1 g IV every 8 hours in addition to single-dose azithromycin. Switching to an oral agent (e.g., cefixime) can occur, once organism susceptibility is confirmed and if clinical improvement is substantial, for a total treatment course of at least 7 days. Patients with gonococcal meningitis or endocarditis should be treated with single-dose azithromycin plus parenteral ceftriaxone *twice daily*, for at least 10 to 14 days (see Table 126.1).[38]

Childhood Infections

Treatment regimens for children weighing >45 kg are the same as for adolescents and adults. In children weighing ≤45 kg, single-dose ceftriaxone (25–50 mg/kg IV or IM with a maximum dose of 250 mg IM) is recommended for treatment of uncomplicated vulvovaginitis, cervicitis, urethritis, pharyngitis, or proctitis; higher weight-based dosing (50 mg/kg) is used to treat conjunctivitis (as a single dose), as well as disseminated infections including bacteremia, arthritis, meningitis, and endocarditis (minimum 7 days; see Table 126.1).[38,82] No data exist regarding the use of dual therapy for treating children ≤45 kg with gonococcal infection.

Special Considerations

PID, a spectrum of inflammatory disorders of the female upper genital tract, can comprise any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. Women who have gonococcal versus nongonococcal salpingitis are more likely to be febrile, to appear acutely ill, and to seek medical attention during the first 3 days of symptoms, although laparoscopic studies have shown that the severity of tubal disease is similar in gonococcal versus nongonococcal disease.[94] In PID, isolation of *N. gonorrhoeae* from the cervix does not necessarily mean that it is the sole pathogen. Acute perihepatitis (Fitz-Hugh–Curtis syndrome) can occur with gonococcal or chlamydial infections. PID is the most common complication of gonorrhea in women, and it occurs in approximately 10% to 20% of women with infection.[95,96] Even asymptomatic infections can progress to PID. Prevention of PID is critical because of potential long-term consequences: tubal infertility, ectopic pregnancy, and chronic pelvic pain.

Without treatment, gonococcal urethritis usually resolves spontaneously over several weeks, and >95% of untreated patients become asymptomatic within 6 months.[19] Most men with gonococcal epididymitis also have overt urethritis.[19] Epididymitis currently is an uncommon complication, and acute or chronic gonococcal prostatitis occurs rarely. Other unusual local complications of gonococcal urethritis include edema of the penis secondary to dorsal lymphangitis or thrombophlebitis, periurethral abscess or fistulas, seminal vesiculitis, and balanitis in uncircumcised men.

The manifestations of gonorrhea during pregnancy are not distinctive, except that pharyngeal infections appear to be more prevalent and PID probably is less common.[19,97] Reported complications in pregnancy include spontaneous abortion, premature rupture of membranes, premature delivery, intrauterine growth retardation, and acute chorioamnionitis, in addition to infection in the neonate.[19,97]

In immunocompromised people such as HIV-infected patients, the manifestations and sequelae of gonococcal infections are not different from or more common than in HIV-uninfected patients. However, nonulcerative STIs enhance HIV transmission by three- to fivefold, in part because of increased viral shedding by people with urethritis or cervicitis. Gonococcal infection also can increase the risk for acquisition of HIV, with the presence of significantly increased numbers of HIV-susceptible CD4$^+$ T lymphocytes and dendritic cells the hypothesized mechanism.[98]

Complement deficiencies, particularly of components involved in the assembly of the membrane attack complex (C5–C9), predispose to *Neisseria* BSI generally and are found in up to 13% of patients with DGI.[73,74]

Prevention and Control

Ocular Prophylaxis

Ocular prophylaxis with topical silver nitrate (1% aqueous solution), erythromycin (0.5%), or tetracycline (1%) ophthalmic ointment reduces the incidence of gonococcal ophthalmia neonatorum with equivalent efficacy.[82,99] Insufficient data exist to recommend 2.5% povidone-iodine for standard prophylaxis in the US.[38,100] Topically applied antibiotics are less irritating than silver nitrate but are slightly more expensive, and they have been associated with emergence of gonococcal resistance.[101] Silver nitrate and tetracycline ophthalmic ointment are no longer manufactured in the US, thus leaving erythromycin ophthalmic ointment as the only recommended agent for ocular prophylaxis.[10] Single-use tubes or ampules are recommended, and prophylaxis should be administered as soon as possible to all newborn infants after delivery.[38,82] If erythromycin ointment is not available, infants at risk for *N. gonorrhoeae* (especially those born to a mother with untreated gonococcal infection or who has not received prenatal care) can be given ceftriaxone 25 to 50 mg/kg IV or IM, not to exceed 250 mg, in a single dose. Properly administered ocular prophylaxis can fail to prevent infection acquired before delivery as a result of prolonged rupture of membranes or infection acquired after administration of prophylaxis. Prophylaxis does not eliminate neonatal nasopharyngeal colonization by *C. trachomatis*, and its efficacy for prevention of chlamydial ophthalmia is unclear.[38]

Partner and Expedited Partner Therapy

All sex partners within the 60 days preceding symptom onset or gonorrhea diagnosis (or, if none, the most recent sex partner) should be examined and treated presumptively.[38] For heterosexual patients whose providers are concerned about partners' access to prompt clinical evaluation and treatment, extended partner therapy (EPT) with cefixime 400 mg and azithromycin 1 g can be delivered to partners by the patient, a disease investigation specialist, or a collaborating pharmacy as permitted by law.[102] Randomized controlled trials demonstrated the safety and noninferiority of EPT versus traditional care in heterosexual patients.[103] The American Medical Association,[104] the American Academy of Pediatrics, the American Academy of Family Physicians,[105] the American College of Obstetricians and Gynecologists,[106] and the Society of Adolescent Health and Medicine[107] endorse EPT for heterosexual patients when in-person evaluation and treatment are impractical or unsuccessful. Partners, however, should be encouraged to seek clinical evaluation to optimize management of STIs. Because of the high risk for coexisting undiagnosed STIs including HIV infection in MSM, EPT is not considered a routine partner management strategy for this patient group.[38]

Screening as Prevention

Because gonococcal infections may not be associated with overt symptoms, particularly in women, annual screening of sexually active women <25 years of age and older women at increased risk for infection is important to prevent disease and sequelae.[38,108] These groups include the following: women who have a new sex partner, more than 1 sex partner, a sex partner with concurrent sex partners, or a sex partner who has an STI; use condoms inconsistently and are not in mutually monogamous relationships; have previous or coexisting STI; exchange sex for money or drugs; are members of a higher-prevalence population or living in an area of higher prevalence. Active gonococcal screening programs decrease the prevalence of *N. gonorrhoeae* infections. Although the US Preventive

Services Task Force has not defined high-prevalence area, a threshold of 4.75% has been cited as a level for cost-effectiveness for screening of women <25 years old who have risk factors (previous gonococcal infection, other STIs, new or multiple sex partners, inconsistent condom use, commercial sex work, and drug use).[109] Frequent rescreening in previously infected people is important; reinfection rate is high (median, 7% in male patients and 12% in female patients).[110,111] Sexually active MSM should be screened at least annually, preferably using NAAT on specimens (urine, rectal swab, or pharyngeal swab) from all sites involved in intercourse. More frequent STI screening at 3- to 6-month intervals is indicated for MSM if risk behaviors persist or if they or their sexual partners have multiple partners.[38] Screening only for urethral infections in MSM would miss up to 95% of gonococcal infections in asymptomatic MSM.[112] Pregnant women at risk or living in an area with high prevalence should be screened for *N. gonorrhoeae* infection at the initial antenatal visit. Those pregnant women found to have gonococcal infection should be treated immediately and retested within 3 months. At-risk patients (including those found to have gonococcal infection) should be screened again during the third trimester.[38]

Vaccination

Although understanding of the pathobiology and immunology of gonorrhea has advanced, limits to knowledge about what constitutes protective immunity, lack of a suitable animal model that mirrors human disease, and previous gonococcal vaccine trial failures have hampered vaccine development.[8,113] Multiple immunogens or adjuvants will likely be required in any *N. gonorrhoeae* vaccine to protect against diverse strains.[8,113,114]

Key Points

Diagnosis and Management of *Neisseria gonorrhoeae* Infections

Microbiology

- *Neisseria gonorrhoeae* is an oxidase-positive, gram-negative diplococcus.

- It requires chocolate agar or other enriched media and carbon dioxide for initial growth in vitro.

- Penicillin, tetracycline, and fluoroquinolone resistance is well described.

- Emerging cephalosporin resistance is identified worldwide.

Epidemiology

- Highest prevalence is in adolescents and young adults 15 to 24 years of age.

- Prevalence of gonorrhea in a community is sustained by continued transmission by asymptomatically infected people and by “core group” transmitters.

- Transmission is primarily sexual (oral, rectal, genital contact) or perinatal during deliver.

- Infection often is localized to the site of inoculation but can disseminate.

Diagnosis

- Most diagnoses are made by nucleic acid amplification testing of urine, or urethral, vaginal, cervical, rectal, or pharyngeal swabs.

- Maintaining culture capability to isolate *N. gonorrhoeae* remains critical as the only method to monitor development of resistance to current antimicrobial treatment regimens.

- Screening and rescreening of at-risk people (e.g., sexually active women <25 years, and men who have sex with men) is strongly recommended.

Treatment

- Ceftriaxone plus azithromycin is recommended therapy for most gonococcal infections because of enhanced treatment efficacy and potential slowing of the emergence and spread of resistance to cephalosporins.

- Susceptibility to other cephalosporins is variable (heterogeneous mechanisms of resistance).
- Sex partners within 60 days of onset of patient's symptoms should be examined and *treated presumptively*.

Other *Neisseria* Species

Zoon Wangu, Katherine K. Hsu

Currently 25 known *Neisseria* species have been isolated in humans and animals. *Neisseria gonorrhoeae* and *N. meningitidis* are the 2 pathogenic *Neisseria* species. Other *Neisseria* species are common commensal inhabitants of the upper respiratory tract and oral cavity of humans and other animals, but they have been implicated in clinical disease in occasional cases, particularly in immunocompromised patients.[1–3] The focus of this chapter is these *Neisseria* species, as well as species that previously have been misidentified as either of the pathogenic *Neisseria* species.

Microbiology and Laboratory Diagnosis

Neisseria species are gram-negative, oxidase-positive bacteria. All are catalase positive, except some strains of *N. bacilliformis* and *N. elongata*. All are diplococci, except *N. bacilliformis* and *N. elongata*. Whereas meningococci and gonococci require additional carbon dioxide for optimal growth and grow only at temperatures of 30°C to 37°C, the other species are less fastidious, growing without added carbon dioxide and at 22°C to 25°C. Unlike *N. gonorrhoeae* and *N. meningitidis,* the other *Neisseria* species (except *N. lactamica*) generally do not grow on selective media such as Thayer-Martin agar; LBVT.SNR medium is used to isolate commensal species.[4] Commensal and pathogenic species usually can be distinguished by biochemical and serologic tests. Carbohydrate use reactions, production of polysaccharide from sucrose, and reduction of nitrate are commonly used for identification (Table 127.1).[2–6] Difficulties in accurate identification of certain species resulted in some confusion and incorrect identifications in earlier published reports.[2]

TABLE 127.1

Selected Characteristics of *Neisseria* Species

Species	Morphology	Pigment	Polysaccharide Synthesis	Acid Produced From				Re of
				Glucose	Maltose	Sucrose	Lactose	
Neisseria gonorrhoeae	Diplococci	−	−	+[a]	−	−	−	−
Neisseria meningitidis	Diplococci	−	−	+	+	−	−	−
Neisseria bacilliformis	Bacilli	+	−	−	−	−	−	+/
Neisseria cinerea	Cocci in pairs or clusters	+/−	−	−	−	−	−	−
Neisseria elongata	Bacilli	+	−	+/−	−	−	−	−
Neisseria flavescens	Cocci in pairs or tetrads	+	+	−	−	−	−	−
Neisseria lactamica	Diplococci	+	−	+	+	−	+	−
Neisseria mucosa	Diplococci	+/−	+	+	+	+	−	+
Neisseria oralis	Cocci in chains	+	?	+/−	+/−	+/−	+/−	+
Neisseria polysaccharea	Diplococci	−	+	+	+	−	−	−
Neisseria sicca	Cocci in pairs or tetrads	+/−	+	+	+	+	−	−
Neisseria skkuensis	Cocci	+	?	+	−	+	−	−
Neisseria subflava	Cocci in pairs or tetrads	+	+/−	+	+	+/−	−	−

[a] Some *N. gonorrhoeae* strains are weak acid producers and may appear to be glucose negative.

+, strains typically are positive, but mutations lacking the specific enzyme activity are found occasionally; −, most strains are negative; +/−, strains are variable.

Epidemiology

Neisseria species commonly colonize the upper respiratory tract and occasionally the genital tract. In a study evaluating carriage rates of 2 *Neisseria* species in healthy infants and children, the prevalence of *N. lactamica* carriage was 3.8% at 3 months of age, peaked at 21% at 18 months of age, and declined to 1.8% by early adolescence.[7] In contrast, the rate of *N. meningitidis* carriage was 0.7% in the first 4 years of life and increased to 5.4% by early adolescence. Similarly, among 1400 healthy children 0 to 10 years of age in Turkey, 17.7% of these children were colonized with *N. lactamica,* whereas only 1.2% were colonized with *N. meningitidis.*[8] Similar results were found in a study of 1- to 29-year-old male and female study subjects in Burkina Faso.[9] Carriage of nonpathogenic strains can be important because *N. meningitidis* and *N. lactamica* share cross-reactive carbohydrate antigens; carriage of *N. lactamica* is likely associated with the development of "natural" immunity against *N. meningitidis*.[10] Cross-reacting antibodies to *N. meningitidis* were found in 66% of children who had asymptomatic colonization with *N. lactamica,* compared with 5% of children who were not colonized.[7] Moreover, inhibition of meningococcal carriage of multiple sequence types was demonstrated following nasal inoculation of *N. lactamica* into university students.[11] *N. lactamica*–based vaccines are being evaluated as a potential strategy to prevent meningococcal disease.[11–14]

Most adults are colonized, either densely or sparsely, by 2 or 3 *Neisseria* strains. For example, oropharyngeal cultures from patients in a clinic for sexually transmitted infections revealed *N. subflava* (biovar *perflava*) in >95%; *N. cinerea, N. mucosa,* and *N. subflava* (biovar *flava*) were found in 25%; and *N. lactamica* in 1%.[15]

Clinical Manifestations

Information on clinical disease caused by commensal *Neisseria* species is accrued primarily through case reports. Characteristics of various species of human origin and some infections caused by the organisms are briefly described here; species of animal origin causing human disease (e.g., *N. animaloris*, *N. canis*, *N. weaver,* and *N. zoodegmatis*) are not discussed. Antibiotic susceptibility testing should be performed on all clinically relevant isolates because some organisms are penicillin resistant secondary to β-lactamase production or altered penicillin binding proteins.

Neisseria bacilliformis.

Strains of *N. bacilliformis* grow as light grey colonies that resemble *N. elongata* on sheep blood agar or chocolate agar at 35°C with 5% carbon dioxide. *N. bacilliformis* is one of a few bacillary *Neisseria* species isolated from humans. *N. bacilliformis* does not produce indole, and reactions in catalase, nitrate reduction, and tributilin tests vary by strain. Sequencing of the 16S ribosomal RNA (rRNA) gene is the most reliable way to identify *N. bacilliformis*.[6]

N. bacilliformis predominantly causes infections of the oral cavity and respiratory tract in immunocompromised people, but cases of native valve endocarditis have been reported in previously healthy men.[16,17]

Neisseria cinerea.

N. cinerea grows as translucent yellow colonies that closely resemble *N. gonorrhoeae*. Misidentification as *N. gonorrhoeae* also can occur when these strains are grown on gonococcus-selective media (e.g., Martin-Lewis medium)[18] or when the Bactec (Becton, Dickinson, Franklin Lakes, NJ) radiometric system is used for detection of glucose use.[19] However, susceptibility to colistin and the ability to grow in trypticase soy broth or Mueller-Hinton agar are characteristics of *N. cinerea* and not *N. gonorrhoeae.*

N. cinerea has been isolated from the oropharynx and nasopharynx and, rarely, from the genital tract. Infections attributed to this species includes hospital-associated pneumonia, cavitary pneumonia and chronic cervical lymphadenitis in immunocompromised patients,[20–22] dialysis-associated peritonitis,[23] bloodstream infection, endocarditis, proctitis, orbital cellulitis, and conjunctivitis.[24–27] In some cases, the isolate was initially misidentified as *N. gonorrhoeae.*

Neisseria elongata.

N. elongata is rod shaped and elongates into filaments when exposed to sublethal concentrations of penicillin. Currently identified subspecies include *N. elongata* subsp. *elongata*, *glycolytica*, and *nitroreducens*, all of which have been reported to cause human disease. Multiple reports exist of *N. elongata,* particularly subsp. *nitroreducens*, as a cause of endocarditis,[28–35] and 1 case was associated with septic emboli and brain abscess.[36] Many of these infections followed dental procedures and occurred in people with preexisting heart disease; the infection frequently caused valvular damage that required surgical intervention. Other infections associated with *N. elongata* include bloodstream infection, osteomyelitis, and dialysis-related peritonitis.[29,37]

Neisseria flavescens.

N. flavescens, a yellow-green-pigmented strain, does not use carbohydrates. This species has been recovered in patients with meningitis, endocarditis, and necrotizing pneumonia with empyema.[38–40]

Neisseria lactamica.

N. lactamica resembles *N. meningitidis* in the following ways: colony morphology; growth on selective media containing vancomycin, colistin, and trimethoprim; and production of acid from glucose and maltose. *N. lactamica* is differentiated by its ability to produce β-galactosidase, which can cleave lactose to glucose; this process causes a color change when *o*-nitrophenyl-β-D-galactopyranoside medium is used.

N. lactamica colonizes the nasopharynx, especially of infants and children,[7–9] and rarely the genital tract.[41] *N. lactamica* has caused meningitis in infants and children, as well as in adults including 1 patient with cerebrospinal fluid leak secondary to fracture of the cribriform plate,[42–44] cavitary lung disease in an organ transplant recipient,[45] bacteremic pneumonia in a patient with cirrhosis,[46] and arthritis and septicemia with myeloma in a patient receiving corticosteroids.[47]

Neisseria mucosa.

N. mucosa is an encapsulated organism that forms large, colorless, moist, mucoid colonies on blood and chocolate agar. It can be differentiated from other species (except *N. oralis*) by its ability to reduce nitrate to nitrite and gaseous nitrogen. Reports of infection include postpneumonectomy empyema, endocarditis, purulent pericarditis, meningitis, peritonitis, and neonatal conjunctivitis.[48–56] In patients with chronic granulomatous disease, *N. mucosa* has caused pneumonia (a pulmonary coin lesion[57]) and visceral botryomycosis.[58]

***Neisseria oralis*.**

Seven strains of a novel *Neisseria* species were reported in 2013.[59] Colonies are small, circular, raised, moist, and yellow, and they are weakly α hemolytic on trypticase soy agar supplemented with 5% sheep blood. Cocci sometimes form chains. All strains reduce nitrate, produce acid from carbohydrates; some strains variably produce β-galactosidase and ferment lactose, characteristics formerly considered unique to *N. lactamica*.

N. oralis has been isolated from blood, subgingival biofilm, urine, and paracentesis fluid. 16S rRNA gene sequencing and DNA-DNA hybridization show similarity to *N. lactamica* but identify *N. oralis* as a novel species.[59] Additional analysis, including whole genome sequencing, indicate that *N. oralis*, although phylogenetically distinct, is most closely related to *N. mucosa*.[4]

***Neisseria polysaccharea*.**

Neisseria polysaccharea, a nonencapsulated *Neisseria* species, produces polysaccharide from sucrose and acid from glucose and maltose. Although its biochemical reactions are similar to those of *N. lactamica* and *N. meningitidis, N. polysaccharea* is distinguished by its unique production of polysaccharide. Some *N. polysaccharea* strains can grow on colistin-containing selective media (i.e., Thayer-Martin).[60] By matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS), *N. polysaccharea* can be misidentified as *N. meningitides*; verification should use biochemical methods.[61] The organism has not been implicated in disease, although its *absence* has been shown to be a risk indicator for periodontal disease.[62]

***Neisseria sicca*.**

N. sicca, a variably pigmented species, grows on agar in dry, wrinkled colonies but rarely grows on gonococcus-specific media because of its susceptibility to colistin. *N. sicca* colonizes the upper respiratory tract and can be responsible for inflammation of oral mucous membranes.[63] Ascribed infections include meningitis,[52] meningitis as a complication of ventriculostomy, or shunt endocarditis, endocarditis with spondylodiscitis, pneumonia, peritonitis, liver abscess complicating transcatheter arterial embolization, and vertebral osteomyelitis.[64–78]

Neisseria skkuensis.

N. skkuensis grows in light grey colonies on sheep blood agar and can be distinguished from most other *Neisseria* species by its ability to produce acid from glucose and sucrose only; it does not reduce nitrate. *N. skkuensis* has been associated with bacteremic diabetic foot infection[79,80] as well as with prosthetic valve endocarditis in an adult with cirrhosis who was undergoing hemodialysis.[81]

Neisseria subflava.

N. subflava, a yellow-pigmented species, grows in smooth and opaque colonies on selective (modified Thayer-Martin) agar. Common inhabitants of the respiratory and genitourinary tracts, the former species *N. subflava, N. flava,* and *N. perflava* have been reclassified as a single species, *N. subflava.*[2] *N. subflava* and *N. sicca* have identical patterns of acid production and similar pigmentation and can be misidentified.[82,83] *N. subflava* has been the cause of bacteremia with cutaneous nodules in an immunocompromised adolescent,[82] meningitis after intrathecal contrast injection,[83] and other rare cases of bloodstream infection, meningitis, endocarditis, epidural abscess-diskitis-vertebral osteomyelitis, and endophthalmitis.[84–91] In children, *N. subflava* can cause fulminant infection that is associated with a petechial or purpuric rash and results in death in approximately one third of cases. Thus, infection with *N. subflava* can be clinically indistinguishable from infection with *N. meningitidis,* and because the strains have similar fermentative patterns, identity can be confused without additional testing.[84]

Special Considerations and Prevention

Misidentification of “other” *Neisseria* species as *N. meningitidis* can result in the unnecessary administration of antibiotic prophylaxis and unwarranted concern in the community regarding potential spread of meningococcal infection. The misidentification of these species as *N. gonorrhoeae* can have important social and medicolegal ramifications, particularly in children.

Several studies have examined the potential role of commensal *Neisseria* as a reservoir for transferring β-lactam antibiotic resistance to pathogenic *Neisseria* strains.[92,93] A 25.2-md conjugative plasmid, similar to that isolated from *N. gonorrhoeae,* has been found in some tetracycline-resistant isolates of *N. meningitidis.* By contrast, some tetracycline-resistant strains of *N. subflava* and *N. mucosa* appear to carry the *TetM* determinant in the chromosome.[94] In addition, *N. subflava* isolates have shown broader resistance to penicillin, cephalosporins, or ciprofloxacin and may be involved in the emergence of resistant *N. gonorrhoeae* strains through horizontal genetic exchange of the *penA* gene.[95] Further studies and surveillance for changes in resistance patterns are important.

Arcanobacterium haemolyticum

Denise F. Bratcher

Arcanobacterium haemolyticum was first identified as *Corynebacterium haemolyticum* in 1946 in pharyngeal cultures of World War II soldiers and Pacific Islanders with pharyngitis that was indistinguishable clinically from infection caused by group A *Streptococcus*.

Epidemiology

Humans are the primary reservoir of *A. haemolyticum*, where the organism is found in the pharynx and on the skin. Although many studies reporting an association of *A. haemolyticum* with pharyngitis failed to exclude viral pathogens and *Mycoplasma pneumoniae, A. haemolyticum* has been implicated increasingly in association with pharyngitis (reported incidence of 0.3%–9.3%) and rash in older children and young adults, with an increased incidence reported among adolescents 15 to 18 years of age.[1] Multiple case reports document infection at pulmonary and extrapulmonary sites. A slight predominance in girls and women is noted among reported pharyngitis series, but a male predilection is noted in systemic *A. haemolyticum* infections.[2,3] Transmission occurs from person to person purportedly by droplet transfer[4]; the incubation period is uncertain.

Microbiology

A. haemolyticum is a gram-positive or gram-variable, pleomorphic, nonmotile, nonsporulating bacillus. It appears strongly gram positive in young cultures and becomes gram variable after 24 hours. Optimum growth occurs on human or rabbit blood agar and is enhanced in carbon dioxide; after 48 hours of incubation, colonies on horse or sheep blood agar (the preferred medium for throat cultures) are small (0.1–0.5 mm), with a narrow zone (1 mm) of hemolysis. A black, opaque dot appears at the center of each colony, and a tiny, dark pit remains if the colony is scraped aside. In clinical isolates, smooth and rough colonies have been noted.[5] *A. haemolyticum* resembles *Corynebacterium diphtheriae* on Löffler medium, whereas poor growth on tellurite medium and lack of catalase distinguish *A. haemolyticum*. The organism also ferments glucose and maltose, usually within 4 days. Production of a dermonecrotic toxin has been demonstrated.

Many cases of *A. haemolyticum* pharyngitis can go undetected because of the slow growth (≥72 hours) in culture and if streptococcal antigen testing is performed without a backup throat culture.

Clinical Manifestations

A. haemolyticum is reported most frequently in association with pharyngitis in people 10 to 30 years old. Most patients complain of mild fever and sore throat. Some have persistent or recurrent pharyngeal symptoms for weeks before diagnosis. Pharyngeal erythema is present universally, and tonsillar exudate is common, occurring in up to 70% of cases. Membranous pharyngitis mimics diphtheria.[6] Lymphadenopathy occurs in 26% to 81% of reported patients, primarily involving the anterior cervical or submandibular lymph nodes bilaterally.

An associated rash (only in patients with pharyngitis) was noted in 23% to 75% of cases reported, most frequently involving the extensor surfaces of the extremities, the neck, and trunk; face, palms, and soles typically are spared, although a single case report of vesicular lesions of the palms and soles exists.[4] The exanthem, commonly described as a scarlatiniform rash (erythematous, blanching fine papules), usually develops 1 to 4 days after the onset of sore throat, although rash has been noted before the development of pharyngitis.[6] Pruritus occurs in approximately 50% of patients, and urticaria and erythema multiforme have been described.[6] Mild desquamation of the skin on the hands and feet follows illness.

In both healthy and immunocompromised hosts, *A. haemolyticum* is the cause of sporadic invasive infections, including septicemia, endocarditis, septic emboli, jugular vein thrombosis (Lemierre syndrome), peritonsillar abscess, meningitis, brain abscess, pneumonia, pleural effusion, sinusitis, urinary tract infections, pelvic abscess, spontaneous bacterial peritonitis, and bone and joint infections.[7–28] Cellulitis, cutaneous abscesses, skin ulcers, wound infections, a paravertebral abscess, and paronychia also have been reported.[7,24,29–35] Chorioamnionitis caused by *A. haemolyticum* was reported in a 19-year-old mother who delivered a healthy infant.[36]

Most invasive *A. haemolyticum* infections that are reported among children also occur in adolescents. These infections include septicemia, brain abscess, pneumonia, empyema, peritonsillar abscess, thyroid abscess, sinusitis associated with orbital cellulitis, and membranous pharyngitis.[a] Endocarditis complicated by cerebral emboli was described in a young woman with congenital heart disease.[41] Septicemia has been reported rarely in adolescents with Epstein-Barr virus infections.[8,42] Coinfection of *A. haemolyticum* with *Fusobacterium necrophorum, Streptococcus agalactiae, Streptococcus milleri, Staphylococcus aureus, Bacteroides* species, *Veillonella* species, *Mycobacterium tuberculosis*, and *Mycoplasma pneumoniae* has been reported.[b]

Diagnosis

The diagnosis is made when *A. haemolyticum* is isolated from a clinical specimen. Pharyngeal isolates of *A. haemolyticum* can be confused with streptococci or *C. diphtheriae* or may be disregarded because colonies are confused with those of normal oral flora. Group A *Streptococcus* and other streptococci have been isolated concomitantly with *A. haemolyticum* from pharyngeal specimens. If *A. haemolyticum* infection is suspected, particularly in an adolescent or young adult with pharyngitis and exanthem, consideration should be given to inoculating agar containing human or rabbit blood or to holding cultures on sheep blood agar for ≥72 hours, in an effort to identify the small hemolytic colonies of *A. haemolyticum.* Use of trypticase soy agar with 5% horse blood in 5% carbon dioxide detected *A. haemolyticum* at 48 hours consistently in 1 study.[45] Modern techniques such as 16S ribosomal RNA (rRNA) amplification and gene sequencing, denaturing high-performance liquid chromatography (DHPLC), and matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) can provide more specific methods of identification.[3,34,41,46] Mild leukocytosis with neutrophilia is common. Biopsy of skin lesions shows only a mild lymphohistiocytic perivascular infiltrate.

Treatment

Neither the benefit of antimicrobial treatment of *A. haemolyticum* pharyngitis nor the comparative efficacy of therapeutic agents has been established in prospective, randomized clinical trials. In case reports, *A. haemolyticum* isolates are susceptible in vitro to penicillin, erythromycin, cefotaxime, cephalothin, chloramphenicol, clindamycin, and tetracycline.[47,48] Bacteriologic failure has been reported after penicillin treatment of pharyngitis and sinusitis,[49] although the significance of persistent colonization is uncertain. *A. haemolyticum* can invade respiratory epithelial cells, thereby potentially creating an intracellular reservoir; in the laboratory, erythromycin kills intracellular bacteria more efficiently than does penicillin.[50] Empiric therapy for pharyngitis with erythromycin or other macrolides is effective against *A. haemolyticum*.[51]

Anecdotal experiences with extrapharyngeal infections with *A. haemolyticum* typically report resolution with intravenous therapy with penicillin G. Tolerance of *A. haemolyticum* to bactericidal effect of penicillin is described among pharyngeal isolates in vitro.[47] Clinical significance of tolerance has been described in an *A. haemolyticum* strain causing endocarditis.[12] Minimum inhibitory concentrations by Etest (Biodisk, Sweden) of 10 invasive *A. haemolyticum* strains determined that all isolates were susceptible to penicillin, cephalosporins, macrolides, clindamycin, ciprofloxacin, and vancomycin but resistant to trimethoprim-sulfamethoxazole.[52] Resistance to ciprofloxacin, tetracycline, and vancomycin has been reported.[3,20,50] Suggested treatment options for pharyngitis include high-dose penicillin plus an aminoglycoside,[12] broad-spectrum β-lactam antibiotics, clindamycin, and macrolides.[9] Antimicrobial treatment of extrapharyngeal infections caused by *A. haemolyticum* is based on the susceptibility pattern of a specific isolate and testing for penicillin tolerance (or avoidance of β-lactam antibiotics).

Key Points

Diagnosis and Management of *Arcanobacterium haemolyticum* Infection

Microbiology

Gram-positive or gram-variable, pleomorphic, nonmotile bacillus

Grows best on human or rabbit blood; enhanced growth in carbon dioxide

Requires ≥72 hours to grow in culture on sheep blood agar and can be missed in routine handling of throat cultures

Epidemiology

Implicated increasingly in association with pharyngitis and rash

Increased incidence reported among adolescents compared with young children

Clinical Manifestations

Typical presentation: sore throat, mild fever, and an erythematous papular rash

Examination reveals: pharyngeal erythema (often with exudate), cervical lymphadenopathy, (frequent) and scarlatiniform rash (frequent)

Causes occasional sporadic invasive infection in healthy and immunocompromised hosts

Coinfection with other respiratory pathogens reported

Diagnosis

Recovery in culture from clinical specimens

Consider holding cultures on sheep blood agar for 72 hours or inoculating onto agar containing human or rabbit blood

Treatment

Suggested treatment for pharyngitis includes penicillin, other ß-lactam agents, clindamycin, and macrolides.

Bacillus Species (Anthrax)

Denise F. Bratcher

Bacillus species, ubiquitous in the environment, are found in soil, water, dust, and air. With the exception of *B. anthracis,* which causes anthrax, *Bacillus* spp. previously have been considered nonpathogenic when isolated from clinical specimens. However, nonanthrax species are increasingly recognized as pathogens in immunosuppressed people and in patients with indwelling devices. Isolates are more likely to be significant if the organism is present on a direct smear of the original specimen or is isolated repeatedly from blood cultures.[1]

In addition, *B. anthracis* has long been recognized as a potential biologic weapon.[2] In the fall of 2001, the deliberate release of *B. anthracis* through the US Postal System provided experience in the clinical presentation, diagnosis, prophylaxis, and treatment of anthrax disease following a bioterrorism-related outbreak.

Immediate notification of the local hospital epidemiologist, the local or state health department, and local or state health laboratories should occur at the first suspicion of an anthrax illness. When bioterrorism alleging the use of anthrax or other agents occurs, the local emergency response system should be activated or local law enforcement agents should be notified.[3] Comprehensive clinical guidance for the unique decisions surrounding prophylaxis and treatment of children following deliberate *B. anthracis* release is provided by the American Academy of Pediatrics (AAP) and the

Centers for Disease Control and Prevention (CDC) Pediatric Anthrax Writing Group.[4]

Microbiology

Bacillus spp. are aerobic or facultatively anaerobic, gram-positive or gram-variable, encapsulated, spore-forming rods that usually are motile. *Bacillus* spp. produce several toxins (including enterotoxin, emetic toxin, phospholipases, proteases, and hemolysins[5]) responsible for much of the morbidity and mortality associated with *B. anthracis*.[4] The species are differentiated by a variety of laboratory observations involving colony morphology, growth on selective media, agglutination reactions, and penicillin susceptibility. *B. anthracis* grows well on blood agar as large, opaque, irregular, “curled-hair” colonies.[6]

Bacillus Anthracis

Epidemiology

B. anthracis, a large, gram-positive, encapsulated, spore-forming, nonmotile rod, is the cause of anthrax. Anthrax, a disease of herbivores that acquire *B. anthracis* while grazing in areas where soil is contaminated by spores, is a zoonotic disease of worldwide occurrence. Disease tends to occur in animals in summer and fall[7]; insects can serve as vectors.[8] Humans typically become infected as they contact infected domestic or wild animals or their products.[7] *B. anthracis* spores can survive for prolonged periods, thus permitting relapsing infection. Human infections have resulted from contact with contaminated products, such as hides, wool, bone meal, and imported dolls, drums, and toys.[9–12] Injection anthrax, associated with use of contaminated heroin, has also been described.[13] Discharge from cutaneous lesions potentially is infectious, and person-to-person transmission is possible. The incubation period is 1 to 7 days but can be up to 60 days depending on host factors, exposure dose, and chemoprophylaxis.

Naturally occurring human disease is rarely reported in the United States.[14] Before the bioterrorism-related anthrax outbreak of 2001, only 18 cases of inhalational anthrax had been reported in the

US in the 20th century.[14] A series of US cases involved exposure to imported animal hides associated with drumming or drum making.[10,11,15]

Clinical Manifestations

Three forms of human disease occur:

1. *Cutaneous anthrax*[16] accounts for most anthrax seen in the US and worldwide; infection follows inoculation of existing skin lesions with *B. anthracis* spores. A painless lesion evolves from a pruritic papule (malignant papule) to a vesicular lesion over 2 to 6 days and eventually forms an eschar (see Fig. 68.7). Striking local edema occurs as a result of release of extracellular toxin, and regional lymphadenopathy and lymphangitis also are noted. Although antibiotic treatment does not alter the progression of an anthrax lesion itself, the mortality rate approaches 20% in patients with untreated cases.

2. *Inhalational anthrax* (wool sorters' disease) results from inhalation of aerosolized spores. A biphasic disease, when it occurs naturally, begins with mild upper respiratory tract symptoms that progress to dyspnea, cyanosis, tachycardia, fever, hypoxemia, shock, and usually death. Bacteremia and hemorrhagic meningitis are common.[17] The chest radiograph typically shows a widened mediastinum consistent with massive lymphadenopathy. This finding in a previously healthy patient with evidence of overwhelming flu-like illness essentially is pathognomonic of advanced inhalation anthrax; pleural effusions also are common. The mortality rate is reported to approach 90%[2]; the case-fatality rate among people who received intensive care in the 2001 attacks was 45%.[18] The first case of naturally acquired inhalation anthrax in the US since 1976 was reported in 2006 in a man who made African drums from imported animal hides.[11] A 2011 inhalational anthrax case with an undefined source involved a 61-year-old man following a vacation and represented only the third naturally acquired case reported in the US since 1976.[19]

3. *Gastrointestinal disease* is a result of ingestion of contaminated, undercooked meat, with deposition of spores in the lower

gastrointestinal tract. Disease manifests as abdominal pain and distention, with vomiting and diarrhea, followed by ascites, hemorrhagic lymphadenitis, and septicemia. An anthrax case involving the gastrointestinal form of disease was reported following animal-hide drum exposure.[9] The mortality rate is 40% or less.[20] *Laryngopharyngeal anthrax* can follow upper gastrointestinal mucous membrane infection acquired from consumption of contaminated meat and manifests as lesions at the base of the tongue or tonsils, dysphagia, profound swelling of the neck, lymphadenopathy, and systemic symptoms.[21,22]

All forms of anthrax can progress to septicemia and meningitis, poor prognostic indicators.[1] Intentional delivery of *B. anthracis* spores through the US mail in 2011 led to 22 cases of anthrax: 11 cases of inhalational and 11 cases of cutaneous anthrax. The patients with inhalational cases likely had direct exposure to a *B. anthracis*–containing envelope. Five patients exhibiting fulminant signs of inhalational illness at presentation died; 6 who came to medical attention less ill received combination antibiotic therapy active against *B. anthracis* and aggressive supportive care and survived. This ~55% overall survival rate is higher than that in previous reports.[24] Fever, chills, fatigue, malaise, and lethargy with minimal or nonproductive cough and nausea or vomiting were common symptoms. Profuse, drenching sweating was a prominent feature. No initial chest radiograph was normal, and pleural effusions were common.

Multiple cases of anthrax have been reported in children, including meningitis, hemorrhagic meningoencephalitis, periorbital cellulitis, neonatal septicemia and meningitis, laryngopharyngeal anthrax, intestinal anthrax, and cutaneous anthrax.[7,12,15,22,25–35] Clinical signs and symptoms in children are nonspecific and variable; the mortality rate is high.[4,22] During the 2001 US Postal Service anthrax outbreak, a 7-month-old infant developed cutaneous anthrax with microangiopathic hemolytic anemia; anthrax spores were identified at his mother's out-of-home office.[36]

Diagnosis

B. anthracis can be isolated from ordinary nutrient broth and on blood agar.[7] Gram stain and culture of vesicular fluid confirm the diagnosis of cutaneous anthrax. Peripheral blood smears can show large, gram-positive bacilli with a "jointed bamboo-rod" appearance; growth in blood culture is positive within 24 hours in inhalational and gastrointestinal anthrax.[4] A direct fluorescent antibody test is available for analysis of a smear of vesicular fluid. Automated blood culture systems readily identify *B. anthracis.* Enzyme immunoassay, immunohistochemistry, and polymerase chain reaction tests are available at state and national reference laboratories (www.cdc.gov/anthrax/labs/labresearch.html). Samples of blood, skin, respiratory secretions, stool, vesicular, pleural, cerebrospinal, or ascitic fluid should be obtained when feasible.[4] The microbiology laboratory should be alerted if anthrax is suspected.

Treatment

Successful management depends on a high index of suspicion and early administration of effective antibiotics. High-dose intravenous penicillin therapy historically has been the drug of choice for all forms of anthrax. Based on more recent data indicating the presence of constitutive and inducible β-lactamases in *B. anthracis* isolates, the use of a penicillin alone for treatment of systemic *B. anthracis* infection is not recommended.[4,37] *B. anthracis* also produces a cephalosporinase, thus inhibiting the use of cephalosporins in treatment.[4,24] Because of concerns regarding genetically engineered *B. anthracis,* the Working Group on Civilian Biodefense recommends that antibiotic resistance to penicillin and tetracycline antibiotics be assumed after a terrorist attack until laboratory testing demonstrates otherwise.[2] Extensive clinical guidance for antimicrobial selection, dosing, supportive care, and prophylaxis of children is provided in the 2014 AAP Clinical Report,[4] and it is summarized in the *Red Book: 2015 Report of the Committee on Infectious Diseases*.[38] Similar comprehensive guidance for adults is provided by the CDC (https://wwwnc.cdc.gov/eid/article/20/2/13-0687_intro).[39]

For cutaneous anthrax, oral ciprofloxacin or doxycycline is considered first-line therapy. If signs of systemic involvement, extensive edema, or head and neck lesions are noted, a multidrug intravenous therapy regimen is recommended. When disease is thought to result from aerosol exposure, antimicrobial therapy is continued for 60 days because of the potential persistence of spores in the respiratory tract. Oral antimicrobial agents can be used for completion of therapy.

Because of the high mortality rate associated with severe systemic anthrax, triple antibiotic therapy given intravenously is recommended for children >1 month of age: 2 bactericidal agents (a fluoroquinolone [ciprofloxacin] *plus* a ß-lactam [meropenem] or glycopeptide [vancomycin]) *plus* a protein synthesis inhibitor (linezolid or clindamycin) to reduce exotoxin production.[4] Alternative regimens are prescribed if meningitis is ruled out or penicillin susceptibility is confirmed. Dosing adjustments are available for infants <1 month of age. Transition to oral combination regimens to complete 2 weeks or more of therapy, based on clinical improvement, is acceptable except for meningitis, which requires 2 to 6 weeks of intravenous therapy. Oral postexposure prophylaxis (PEP) should continue after the initial antimicrobial course to complete a total of 60 days if anthrax resulted from a bioterrorism event.

Other agents with in vitro activity against *B. anthracis* that are suggested for use in multidrug regimens include levofloxacin, moxifloxacin, imipenem, doripenem, vancomycin, penicillin, ampicillin, rifampin, and chloramphenicol. If meningitis is suspected, doxycycline should be avoided because of poor central nervous system penetration. Use of anthrax immune globulin (AIG) was associated with decreased mortality rates in older reports and has been used in more recent inhalational and gastrointestinal anthrax cases.[19,22,40,41] A human monoclonal antibody, raxibacumab, directed against a component of the anthrax toxin has shown improved survival in animal studies of inhalational anthrax.[42] The AAP Clinical Report recommends the addition of an antitoxin product (either AIG or raxibacumab) to combination antimicrobial therapy to treat systemic or progressive disease.[4] Corticosteroid therapy has been suggested for patients with the following: extensive edema, respiratory compromise, and meningitis associated with systemic anthrax; extensive edema of the head and neck region associated with cutaneous anthrax; and adrenal failure.[4,37]

Postexposure Prophylaxis and Prevention

Prevention of naturally occurring human disease depends on control of animal disease and industrial contamination. Contact precautions to prevent transmission from draining wounds and secretions are advised for medical personnel during the first 24 hours of treatment[38] of patients with cutaneous or inhalational anthrax. Contaminated linens should be incinerated or steam sterilized to destroy spores. Autopsies on patients with systemic anthrax require special precautions.

Following a confirmed or suspected aerosol exposure, PEP is indicated for 60 days to prevent inhalational anthrax.[4,43] Initial therapy with ciprofloxacin (30 mg/kg/day divided every 12 hours, maximum 500 mg/dose) or doxycycline (4.4 mg/kg/day divided every 12 hours, maximum 1 g/dose) is recommended for adults and children until antimicrobial susceptibilities of the implicated *B. anthracis* isolate are known. Clindamycin and levofloxacin are alternatives. If penicillin susceptibility is confirmed, oral amoxicillin is appropriate prophylactic therapy for children (75 mg/kg/day divided every 8 hours; maximum dose, 1 g/dose).[44,45] Decisions regarding PEP for pregnant or breastfeeding mothers should be made independent of considerations for the infant.[46] The most current information related to the treatment and PEP is available through the CDC website at www.cdc.gov.

Vaccine for Pre-exposure and Postexposure Prophylaxis

Animal and human vaccines are available.[10,47] The only licensed human anthrax vaccine available in the US is made from the cell-free filtrate of a nonencapsulated, attenuated strain of *B. anthracis* (BioThrax, Emergent BioSolutions, Lansing, Mich).[14] Anthrax vaccine is indicated for workers who contact imported animal hides, hair, or textiles in the workplace and for those involved with military, diagnostic, or investigational work. The current pre-exposure vaccine series consists of 2 intramuscular injections administered 4 weeks apart, followed by 3 subsequent injections at 6, 12, and 18 months, in addition to annual booster doses; administration in the deltoid muscle is recommended.[18] AVA (anthrax vaccine adsorbed) is not currently licensed for use in children but would be available under an Investigational New Drug application if indicated for postexposure administration.[4,14] Postexposure administration includes 3 doses of AVA at 0, 2, and 4 weeks after exposure in the midst of 60 days of antimicrobial chemoprophylaxis for children ≥6 weeks; vaccine is delayed until infants reach 6 weeks of age while antimicrobial chemoprophylaxis is instituted. Local reactions, including edema, erythema, warmth, tenderness, and pruritus, are substantially reduced by intramuscular versus subcutaneous injections. Systemic reactions are rare.

Newer vaccine technologies offer the potential for improved anthrax vaccines, and alternate treatment and prophylactic modalities are under investigation.

Bacillus Cereus

Epidemiology

Bacillus cereus is a significant cause of toxin-induced food poisoning characterized by emesis and diarrhea.[48] From 1998 to 2008, 235 outbreaks of foodborne disease caused by *B. cereus* were reported in the US.[49] Although various foods have been implicated, including infant cereal, contaminated fried rice most frequently is associated with the emetic form of disease, which is caused by heat-resistant, preformed toxin, cereulide, or *B. cereus* spores that germinate when boiled rice is left unrefrigerated[49–52] Nausea, vomiting, and diarrhea with abdominal cramping can occur within 1 to 6 hours of ingestion of contaminated food. The isolated diarrheal form, which is associated with profuse diarrhea produced by an enterotoxin similar to that of *Clostridium perfringens,* has a longer incubation period of 6 to 24 hours. *B. cereus* can be isolated from stools of asymptomatic people, but person-to-person transmission does not occur.[48] Confirmation of food poisoning requires isolation of *B. cereus* from stool or emesis in addition to isolation of *B. cereus* (10^5 colony-forming units/g) in contaminated food.

Clinical Manifestations

B. cereus food poisoning typically is brief and self-limited, requiring no antimicrobial therapy. A few fatal cases caused by *B. cereus* emetic toxin have been reported, including the following: fulminant hepatic failure and rhabdomyolysis in an adolescent after consumption of contaminated pasta[53]; hepatic failure and pulmonary hemorrhage in a 7-year old after consumption of contaminated pasta salad[54]; and acute encephalopathy in a 1-year-old 6 hours after eating reheated fried rice.[55] This last patient and his 2-year old sibling had cereulide detected in serum at presentation; the sibling recovered after plasma exchange and hemodialysis. One child developed fulminant hepatitis, shock, and prolonged seizures associated with *B. cereus* food poisoning,[56] and another presented with acute encephalopathy and features consistent with Reye syndrome.[57]

Multiple other human infections with *B. cereus* have been reported.[4] *B. cereus* ranks as the second most common pathogen of posttraumatic ophthalmitis, after *Staphylococcus epidermidis*.[58,59] The organism typically is introduced by a projectile foreign body or open globe injury, producing a rapidly severe infection that frequently results in enucleation or poor visual outcome. A postsurgical endophthalmitis outbreak has been described, but *B. cereus* is an uncommon cause of postoperative endophthalmitis.[60] Management is aggressive, including surgical intervention and parenteral, intravitreal, and topical antimicrobial treatment.

B. cereus is a cause of clinically significant bloodstream infection and, occasionally, fulminant septicemia in neonates, intravenous drug abusers, and immunocompromised patients, including children with cancer and those with an indwelling catheter or prosthetic device.[4,61–75] Septicemia has followed transfusion of *B. cereus*–contaminated platelets and dietary tea consumption in children with cancer.[76,77] A mortality rate of 31% is reported for *B. cereus* septicemia in patients with hematologic disease. Endocarditis, typically involving a prosthetic valve or the tricuspid valve in intravenous drug abusers, also has been described.[78–81] Pneumonia was reported in immunosuppressed patients and neonates,[4,80,82] and it was associated with fulminant septicemia in 2 previously healthy welders.[83] Hepatic abscess caused by *B. cereus* in a previously healthy teen was noted.[84] Meningitis, hemorrhagic meningoencephalitis, and brain abscess caused by *B. cereus* have been reported, often affecting neonates, immunocompromised children, or children with ventriculoperitoneal shunts.[5,64,80,85–95] Case reports describe the following: hemorrhagic and early, cavitating, selective white matter destruction as typical of neonatal *B. cereus* meningoencephalitis[96]; local infection after burns, trauma, or surgical procedures[97,98]; primary cutaneous infections in neutropenic children[99]; necrotizing cellulitis[100]; osteomyelitis associated with accidental or surgical trauma or intravenous drug abuse[101]; urinary tract infection in a patient with invasive bladder cancer; peritonitis associated with peritoneal dialysis[102–104]; and intestinal diseases in neonates.[105,106] Nosocomial transmission of *B. cereus* is reported,[105,107–112] and 2 children developed *B. cereus* central line–associated bacteremia possibly associated with contaminated alcohol pledgets.[113]

Antibiotic therapy is indicated in invasive *B. cereus* infections, but optimal therapy is not defined. Vancomycin, clindamycin, fluoroquinolones, and carbapenems are used commonly. Antimicrobial susceptibility testing is essential; clindamycin and carbapenem resistance is reported.[72,114] Removal of prosthetic devices usually is necessary for cure and is associated with a significantly lower recurrence rate.[63,72,104,115] Surgical intervention typically is required in ophthalmic infection, brain abscess, and soft tissue infection. Endophthalmitis typically is treated with intravitreal vancomycin, vitrectomy, and topical and systemic fluoroquinolone therapy.

Bacillus Subtilis and Other *Bacillus* Species

Other *Bacillus* spp. implicated in human infections include *B. alvei, B. brevis, B. circulans, B. coagulans, B. infantis, B. idriensis, B. laterosporus, B. licheniformis, B. macerans, B. pumilus, B. sphaericus, B. subtilis,* and *B. thuringiensis*.[a] Nonanthrax *Bacillus* species have been associated with bloodstream infection (including catheter-related infection), brain abscess, meningitis, pneumonia, pleuritis, endocarditis, pericarditis, urinary tract infection, peritonitis, periorbital cellulitis, and ocular infections. *B. thuringiensis* has been associated with foodborne gastrointestinal illnesses.[48] Case reports of infections with *Bacillus* species are sometimes difficult to interpret because the species frequently is identified incorrectly or can represent a contaminant of the culture.

B. subtilis specifically is described in association with bloodstream infection, cholangitis, meningitis, chronic osteomyelitis, panophthalmitis, pneumonia, and ventriculoperitoneal shunt infections.[5,80,124] Unlike *B. cereus, B. subtilis* is susceptible to penicillins in addition to vancomycin, clindamycin, aminoglycosides, and third-generation cephalosporin agents.

Key Points

Bacillus Species

- Nonanthrax *Bacillus* species are increasingly recognized as pathogens in immunocompromised people, especially if the organisms are isolated repeatedly from blood culture or if they appear on a direct smear of the original specimen.

- Naturally occurring anthrax infections usually result from contact with infected domestic or wild animals or their products (e.g., hides, hair).

- Three forms of anthrax disease occur in humans: (1) cutaneous, (2) inhalational, and (3) gastrointestinal. All 3 forms can progress to septicemia and meningitis, and pediatric patients have been reported with all forms of the disease.

- *Bacillus anthracis* grows in standard nutrient broth and on blood agar from blood and clinical specimens.

- Triple antimicrobial therapy is recommended for treatment of systemic anthrax, anchored by bactericidal agents (ciprofloxacin) plus a ß-lactam agent (meropenem) plus a protein synthesis inhibitor (clindamycin).

- Oral ciprofloxacin is considered first-line therapy for cutaneous anthrax.

- Anthrax is recognized as a potential biologic weapon. Guidance for clinical decisions for treatment and postexposure prophylaxis following presumed deliberate *B. anthracis* release is available for adult, pediatric, and pregnant or postpartum patients.

- Anthrax vaccine adsorbed is not currently licensed for use in children but can be a component of postexposure prophylaxis under an Investigational New Drug application, if indicated.

- *B. cereus* is a significant cause of toxin-mediated food poisoning and has been implicated in several other clinically significant human infections, particularly among immunocompromised hosts.

Corynebacterium diphtheriae

Irini Daskalaki

Diphtheria is a toxicosis caused by infection with *Corynebacterium diphtheriae*. The genus and species names are derived from Greek roots: *korynee* ("club") after the microscopic appearance of the organisms and *diphtheria* ("leather hide") for the pseudomembrane that is the hallmark of respiratory tract infection. Once a major cause of childhood death, diphtheria was among the first infectious diseases to be controlled through the use of modern principles of microbiology, immunology, and public health. Increased immunization rates, rare circulation of toxigenic strains, and improved living conditions have controlled diphtheria in developed countries. However, the rare importation of diphtheria into the United States from developing countries and recent outbreaks in developed countries, with significant morbidity and mortality, have underscored the continuing need for diphtheria immunization.

Etiology

Corynebacterium species are aerobic, nonencapsulated, nonspore-forming, mostly nonmotile, pleomorphic gram-positive bacilli. Isolation is enhanced by the use of selective media (e.g., cystine-tellurite blood agar) that inhibit the growth of competing organisms and, when reduced by *C. diphtheriae,* produce colonies that appear grey to black. Modified Tinsdale medium and Löffler or Pai slants are additional effective enrichment media. Growth occurs within 48 hours; Gram staining of typical colonies from Löffler or Pai media can confirm a presumptive identification. Three phenotypes (*mitis, gravis,* and *intermedius*), each capable of causing diphtheria, are distinguished by colonial morphology, hemolysis, and fermentation reactions. A lysogenic bacteriophage that encodes for production of exotoxin confers no essential protein to the bacterium, but factors other than toxin production can cause virulence and facilitate the spread of infection.[1]

Production of diphtheria toxin can be demonstrated in vitro by use of an agar well or antitoxin membrane immunoprecipitin technique (Elek test) or by in vivo toxin neutralization tests in the guinea pig.[2,3] Investigational polymerase chain reaction (PCR) tests detect the presence of genes for both A and B toxin subunits but do not prove toxin production directly.[4] Toxigenic strains are indistinguishable by colony type, microscopy, or biochemical tests. Expression of toxin is enhanced in vitro by nutrient or iron depletion or exposure to ultraviolet light. Nontoxigenic *C. diphtheriae* can be converted to toxigenic strains by lysogenic infection. Studies of outbreaks in which molecular techniques were used suggest that indigenous nontoxigenic *C. diphtheriae* strains can be rendered toxigenic, producing clinical diphtheria, after importation of single cases of toxigenic *C. diphtheriae.*[5] Nondiphtheria strains of *Corynebacterium* (e.g., *C. ulcerans*) can produce diphtheria toxin and cause a respiratory diphtheria-like illness.[6,7]

Epidemiology

Coryneform bacteria ("diphtheroids") are ubiquitous in nature. They are found on human skin and mucous membranes, on plants, in soil, and in freshwater and saltwater. Humans are the only known reservoir of *C. diphtheriae,* although a novel strain was isolated from cats in West Virginia.[8] The primary modes of spread are by airborne respiratory droplets and by direct contact with respiratory secretions or exudate from skin lesions. Asymptomatic or convalescent respiratory carriers are important reservoirs for transmission. In endemic areas 3% to 5% of healthy people harbor toxigenic organisms, but pharyngeal carriage of these strains is uncommon if clinical diphtheria is rare. Skin infection, or carriage, can be the silent reservoir of toxigenic diphtheria. Viability in dust and on fomites for up to 6 months has unknown epidemiologic significance. Transmission by means of animals, contaminated milk, and an infected food handler has been proved or suspected.[9]

Diphtheria occurs worldwide. In temperate climates the incidence is higher during the colder months. The disease remains endemic in many developing countries with inadequate immunization rates, occurring predominantly in poor socioeconomic conditions. In industrialized countries the main risk factor for acquisition of toxigenic *C. diphtheriae* is travel to endemic areas (Asia, South Pacific, Eastern Europe) or laboratory acquisition.[10] A complete list of areas in which diphtheria is endemic is available from the Centers for Disease Control and Prevention (CDC).[11]

Before 1930 more than 125,000 cases and 10,000 deaths caused by diphtheria were reported annually in the United States (incidence, 100 to 200 cases per 100,000). The highest fatality rates occurred among people younger than 5 years of age and those older than 40 years. The widespread use of diphtheria toxoid vaccine in the U.S. after World War II produced a steady decline in the incidence of diphtheria, to 0.001 per 100,000 population; between 2004 and 2015 only 2 cases of diphtheria were reported in the U.S., and since 1988 all cases have been imported.[12]

Although immunization does not prevent respiratory or cutaneous carriage or infection with toxigenic *C. diphtheriae,* neutralization of toxin diminishes local tissue spread, necrosis, multiplication, and transmission, thereby providing herd immunity. It is estimated that 70% to 80% of a population must be immunized to prevent epidemic spread.[13] Even with the low rate of circulating toxigenic *C. diphtheriae* in most industrialized countries, subgroups have been identified that would be at risk if the organism were introduced as a consequence of underimmunization. In a multicenter European study, screening of upper respiratory specimen cultures revealed both toxigenic and nontoxigenic strains of *C. diphtheriae,* indicating carriage in highly vaccinated populations.[14] The National Immunization Survey in the

U.S. has demonstrated that coverage with at least three doses of diphtheria toxoid among children 19 to 35 months old has been approximately 95% for about a decade.[15] However, in serosurveys in the U.S. and western European countries, where childhood immunization is universal, 20% to more than 60% of the people were found to lack protective antitoxin levels (antitoxin level >0.01 IU/mL). The elderly had particularly low levels.[13,16–19]

Low levels of antitoxin in some populations may reflect relatively poor rates of administration of booster diphtheria vaccines after primary immunization in childhood. The recent epidemiology of diphtheria demonstrates a shift from endemic disease in childhood to outbreaks in adults. In 27 sporadic cases of respiratory tract diphtheria in the U.S. in the 1980s, 70% occurred in people older than 25 years.[18] A similar shift of the epidemiology of diphtheria to adult cases has been identified in Europe.[20]

In the 1990s a massive outbreak of diphtheria occurred in the Newly Independent States of the former Soviet Union; more than 150,000 cases occurred within 6 years in 14 of the 15 states.[21] Case-fatality rates ranged from 3% to 23% by state, and more than 60% of cases occurred among people older than 14 years. Factors contributing to the epidemic included a large population of susceptible (i.e., underimmunized) adults, decreased childhood immunization, population migration, crowding, and a failure to respond aggressively during early phases of the epidemic. Attempts to control the epidemic with childhood immunization alone failed, whereas mass immunization of both children and adults was successful. Cases of diphtheria among travelers were transported to many countries in Europe. Molecular characterization of the Russian *C. diphtheriae* isolates by ribotyping and multilocus enzyme electrophoresis demonstrated that the outbreak was caused by a distinct clonal group that emerged in Russia in 1990.[22]

Cutaneous diphtheria may be central to the changing epidemiology of diphtheria. Cutaneous diphtheria has accounted for more than 50% of *C. diphtheriae* isolates reported in the U.S. since 1975. Cutaneous infection is infrequently associated with toxic complications, and it is caused by toxigenic and nontoxigenic strains, often in association with other bacteria. In contrast to respiratory tract infection, cutaneous diphtheria is associated with prolonged bacterial shedding, increased environmental contamination, and increased transmission to close contacts. Outbreaks of cutaneous diphtheria have been associated with homelessness, crowding, poverty, alcoholism, poor hygiene, contaminated fomites, underlying dermatosis, and introduction of new strains from exogenous sources. From 1971 through 1982, a total of 1100 *C. diphtheriae* infections were documented in Seattle; 86% were cutaneous, and 40% involved toxigenic strains.[23] A more recent review from Vancouver found associations with injection drug use and poverty.[24]

Currently cutaneous diphtheria is a reservoir for toxigenic *C. diphtheriae* in the U.S. and has been a frequent mode of importation of source cases for sporadic respiratory tract diphtheria. However, attention has been focused on respiratory tract diphtheria, which is much more likely to cause complications and toxic manifestations, and cutaneous diphtheria has not been a nationally reportable disease since 1980.

Pathogenesis

Both toxigenic and nontoxigenic *C. diphtheriae* organisms cause skin and mucosal infection, in addition to rare distant infection after bacteremia. The organisms remain confined to superficial layers of skin lesions or respiratory mucosa and induce a local inflammatory reaction. The major virulence factor is a potent 62-kd polypeptide exotoxin that consists of a binding segment A and an active segment B which, when cleaved, is internalized and inactivates transfer RNA translocase, preventing the addition of amino acids during protein synthesis. Within the first few days of respiratory tract infection, a dense, necrotic “pseudomembrane” forms, consisting of organisms, epithelial cells, fibrin, leukocytes, and erythrocytes. The pseudomembrane advances and becomes adherent. Removal is difficult and reveals a bleeding, edematous submucosa. Early local effects of the toxin include paralysis of the palate and hypopharynx. Absorption and hematogenous dissemination of the toxin can lead to necrosis of the kidney tubules and hepatic parenchyma, amegakaryocytic thrombocytopenia, myocardiopathy, and demyelinating neuropathy. Cardiomyopathy and neuropathy occur 2 to 10 weeks after the initial mucocutaneous infection and may involve an immune-mediated pathophysiology in addition to delayed appearance of toxic tissue damage.

Clinical Manifestations

Respiratory Tract Diphtheria

In a classic description of 1400 cases of diphtheria, infection involved the tonsils or pharynx in 94%; the nose and larynx were the next two most common sites.[25] After an average incubation period of 2 to 4 days, local signs and symptoms of inflammation develop. Fever is low grade or absent. Infection of the anterior nares (more common in infants) causes serosanguineous, erosive rhinitis with membrane formation. Shallow ulceration of the external nares and upper lip is characteristic. Sore throat is a universal early symptom of tonsillar or pharyngeal diphtheria, but only 50% of patients have fever, and fewer than 50% of patients have dysphagia, hoarseness, malaise, or headache. Mild pharyngeal injection is followed by unilateral or bilateral tonsillar membrane formation, which extends off tonsillar tissues to variably affect the uvula, soft palate, posterior oropharynx, hypopharynx, and glottic areas (Fig. 130.1). Underlying soft tissue edema and enlarged lymph nodes can cause cervical swelling (e.g., bullneck), characterized by obliteration of the borders of the mandible, sternocleidomastoid muscle, and clavicle by brawny, pitting, warm, tender, but nonerythematous edema. The degree of toxin extension correlates directly with symptoms of prostration, bullneck, airway compromise, and subsequent toxin-mediated complications of distant organs. A patient with laryngeal diphtheria is highly prone to acute airway compromise as a result of local edema and the formation of the pseudomembrane. Establishment of an artificial airway and resection of pseudomembrane may be lifesaving.

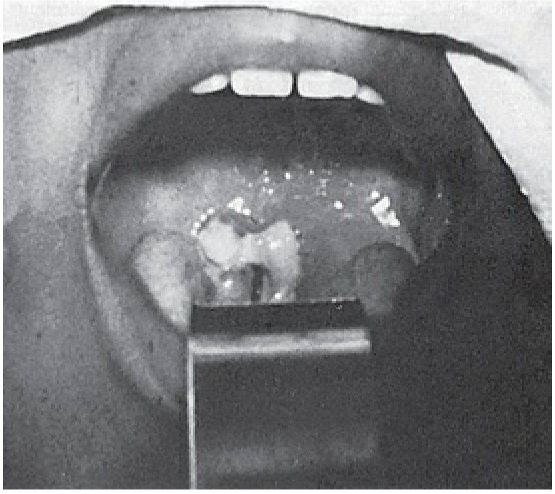

FIGURE 130.1 Four-year-old girl with faucial diphtheria.

The appearance of the leatherlike, adherent pseudomembrane, which extends beyond the faucial tonsillar area, and a relative lack of fever and dysphagia help distinguish diphtheria from the exudative pharyngitis caused by *Streptococcus pyogenes,* adenovirus, and Epstein-Barr virus. The absence of exanthem or ulcers elsewhere on the oral mucosa and tongue distinguishes diphtheria from infections arising from other viral causes. Vincent angina and Lemierre disease, phlebitis and thrombosis of the jugular veins, mucositis in patients undergoing cancer chemotherapy, and a faucial membrane after tonsillectomy usually are distinguished by the clinical setting. Diphtheritic infection of the larynx, trachea, or bronchi can be primary or can occur from secondary extension after pharyngeal infection; hoarseness, stridor, dyspnea, and a croupy cough are clues to infection of these sites. Differentiation from bacterial epiglottitis, severe viral laryngotracheobronchitis, and staphylococcal or streptococcal tracheitis hinges partially on the relative paucity of other signs and symptoms in a patient with diphtheria and primarily on visualization of an adherent pseudomembrane at the time of laryngobronchoscopy and intubation.

Cutaneous Diphtheria

Cutaneous diphtheria usually is an indolent, nonprogressive infection characterized by a superficial, ecthymic, nonhealing ulcer with a grey-brown membrane. Diphtheritic skin infection often cannot be distinguished from streptococcal or staphylococcal impetigo, and the conditions frequently coexist. In the Seattle outbreak,[23] *S. pyogenes* was isolated in 73% of diphtheritic skin lesions. The role of *C. diphtheriae* as the cause of localized findings is not clear. Ulcers do not respond to antitoxin therapy, but infection elicits high antitoxin levels. In most cases, underlying dermatoses, lacerations, burns, bites, or impetigo have become secondarily contaminated. The extremities are affected more often than the trunk or head. Pain, tenderness, erythema, and exudate are typical. Local hyperesthesia or hypoesthesia can occur. Respiratory tract colonization or symptomatic infection, in addition to toxic complications, occur in a minority of patients with cutaneous diphtheria. Of the infected adults in Seattle, 3% of those with cutaneous infections – compared with 21% of those with symptomatic nasopharyngeal infection with or without skin involvement – had toxic myocarditis, neuropathy, or obstructive respiratory tract complications.[23] All had received at least 20,000 units of equine antitoxin at the time of hospitalization.

Infection at Other Sites

C. diphtheriae occasionally causes infections at other mucocutaneous sites, such as the ear (otitis externa), eye (purulent and ulcerative conjunctivitis involving primarily palpebral areas), and genital tract (purulent and ulcerative vulvovaginitis). The clinical setting, ulceration, pseudomembrane formation, and submucosal bleeding help differentiate diphtheritic infection from other bacterial and viral causes.

Rare cases of septicemia caused by *C. diphtheriae* have been described, and such cases often are fatal. Sporadic cases of endocarditis occur, and clusters among intravenous drug users have been reported,[26,27] as have occasional cases in children living in endemic areas.[28,29] Notable clinical features are aggressive valvular destruction with associated pyogenic arthritis and major vascular complications (emboli and aneurysms) caused by the large size of vegetations; most complications have been caused by nontoxigenic strains. Most patients did not have respiratory tract symptoms. Although skin lesions were not described, skin is likely to have been the portal of entry. Sporadic cases of pyogenic arthritis, mainly caused by nontoxigenic strains, have been reported in adults and children.[30] Diphtheroids isolated from sterile body sites should not be dismissed as contaminants without careful consideration of the clinical setting, and they should be identified to the species level if validly associated with invasive disease. If *C. diphtheriae* is isolated, toxigenicity studies of the isolate should be completed and prophylaxis for contacts should be considered.

Toxic Myocardiopathy

Toxic myocardiopathy occurs in approximately 10% to 25% of patients with diphtheria and is responsible for 50% to 60% of deaths. Subtle signs of myocarditis may be detectable in many patients, especially in the elderly, but the risk of significant complications for an individual correlates directly with the extent and severity of exudative oropharyngeal disease and delays in administration of antitoxin.[23,25,26]

Most often the first evidence of cardiomyopathy is recognized in the second to third week of illness, as pharyngeal disease improves. However, cardiomyopathy can appear as early as the first week (the likelihood of a fatal outcome is high) or insidiously, as late as the sixth week of illness. Tachycardia out of proportion to fever is common evidence of cardiac toxicity or autonomic nervous system dysfunction. A prolonged PR interval or ST-segment and T-wave changes are relatively frequent findings on an electrocardiogram, and dilated or hypertrophic cardiomyopathy frequently is observed on an echocardiogram. Single or progressive cardiac arrhythmias can occur, such as first-, second-, and third-degree heart block, atrioventricular dissociation, and ventricular tachycardia. Clinical congestive heart failure can have an insidious or acute onset. Elevation of the serum aspartate aminotransferase concentration closely parallels the severity of cardiac myonecrosis. Severe arrhythmia portends death.[16,25,31] Histologic postmortem findings can show a minor abnormality or diffuse myonecrosis with an acute inflammatory response. Except for survivors of more severe arrhythmias, who may have permanent conduction defects, patients usually recover completely from toxic myocardiopathy.

Toxic Neuropathy

Neurologic complications parallel the extent of primary infection and are multiphasic in onset.[23,25,31] Two to 3 weeks after the onset of oropharyngeal inflammation, hypoesthesia and local paralysis of the soft palate commonly occur. Weakness of posterior pharyngeal, laryngeal, and facial nerves may follow, causing a nasal quality in the voice, difficulty swallowing, and the risk of death from aspiration. Cranial neuropathies usually occur in the fifth week, leading to oculomotor and ciliary paralyses; these manifest as strabismus, blurred vision, or difficulty with accommodation. Symmetric polyneuropathy can have its onset 10 days to 3 months after onset of oropharyngeal infection and principally causes motor defect and diminished deep tendon reflexes.

Both proximal muscle weakness of the extremities that progresses distally, and more commonly, distal weakness that progresses proximally, have been described. The clinical and cerebrospinal fluid findings are indistinguishable from those seen with the polyneuropathy of Guillain-Barré syndrome. Paralysis of the diaphragm can occur, but complete recovery is likely. In rare cases 2 or 3 weeks after the onset of illness, dysfunction of vasomotor centers can cause hypotension or cardiac failure.

Management of Symptomatic Patients

Diagnostic Tests

Specimens for culture should be obtained from the nose and throat and from any affected mucocutaneous site. A portion of the pseudomembrane and the underlying exudate should be removed and submitted for testing. Growth from slants are stained with Neisser stain or Löffler methylene blue and examined for metachromatic granules. When the specimens are submitted, the laboratory must be notified to use selective media for isolation. *C. diphtheriae* survives drying, but if transport to a laboratory will require more than 24 hours, a transport medium should be used. In remote areas a swab specimen can be placed in a silica gel pack and sent to a reference laboratory.

Evaluation of direct smears using Gram stain or specific fluorescent antibody is unreliable. When coryneform bacteria are isolated from sterile body sites or from mucocutaneous sites in suspected cases or contacts, the organisms should be identified to the species level and toxigenicity and antimicrobial susceptibility tests should be performed on *C. diphtheriae* isolates. Although the only commercially available methods to diagnose *C. diphtheriae* infection are culture and toxigenicity tests, the CDC performs a PCR assay that allows detection of the regulatory gene for toxin production *(DTXR)* and the diphtheria toxin gene *(TOX).* This assay provides supportive evidence for the diagnosis; it is not sufficient for confirmation but can be particularly useful if nonviable organisms are present in clinical specimens.[32] Few laboratories measure serum antibodies to the toxin; however, if this is done before antitoxin is administered, it could be helpful in assessing the probability of the diagnosis.

Antitoxin

Specific antitoxin neutralizes only free toxin; therefore, if the clinical findings and epidemiology support the diagnosis, antitoxin should be administered promptly, before culture confirmation. The mortality rate is less than 1% if antitoxin is administered on the first day of disease, but it increases 20-fold if treatment is delayed until the fourth day.

Antitoxin of human origin might be available in some countries, but in the U.S. only an equine preparation is available. Equine diphtheria antitoxin (DAT) is available only from the CDC through an investigational new drug protocol (CDC Emergency Operations Center; 24-hour telephone: 770-488-7100).[33] Antitoxin is administered once at an empiric dosage based on the degree of toxicity, site and size of the pseudomembrane, and duration of illness.[33] The intravenous route is preferred. Antitoxin is probably of no value for local manifestations of cutaneous diphtheria but can be recommended if signs of systemic toxicity are present. Prophylactic treatment with antitoxin for exposed individuals should be considered only in special circumstances. Antitoxin is not recommended for asymptomatic carriers.

The frequency of anaphylaxis and serum sickness is considered to be low in the current era because it is partially influenced by the previous administration of animal serums in the population. However, even patients who are very ill must be tested before infusion of antitoxin, and those who show immediate reactions should undergo a desensitization protocol.[33]

Commercially available immune globulin preparations for intravenous use (IGIVs) contain antibodies to diphtheria toxin, but the amounts likely vary from lot to lot. Their use for therapy of diphtheria has neither been proved nor recommended. Identification of a human monoclonal antibody as a safer and efficacious alternative to antitoxin is under investigation.[34]

Antimicrobial Therapy

Antimicrobial therapy is indicated to limit presumed continuing toxin production, to treat localized infection, and to prevent the transmission of organism to contacts; however, antibiotic therapy is not a substitute for antitoxin therapy. *C. diphtheriae* usually is susceptible in vitro to penicillins, erythromycin, newer macrolides (clarithromycin, azithromycin), clindamycin, rifampin, fluoroquinolones, and tetracycline. Resistance to erythromycin has been documented in cutaneous diphtheria outbreaks in the U.S.[23] Only penicillin and erythromycin have been evaluated in prospective trials, and they are the sole agents recommended. Erythromycin is marginally superior to penicillin for eradication of nasopharyngeal carriage. Appropriate therapy is erythromycin given orally or parenterally (40 to 50 mg/kg/day, maximum 2 g/day); or aqueous crystalline penicillin G intramuscularly or intravenously (100,000 to 150,000 units/kg/day divided into 4 doses) or procaine penicillin intramuscularly (25,000 to 50,000 units/kg/day divided into 2 doses). Therapy is given for 14 days. Some patients with cutaneous diphtheria have been treated for 7 to 10 days. Elimination of the organism should be documented by two successive cultures from the nose, throat, and skin (when appropriate) at least 24 hours apart after completion of therapy. Treatment with erythromycin is repeated if the culture result is positive.

Other Measures

Droplet isolation is recommended for patients with pharyngeal diphtheria; contact isolation is sufficient for patients with cutaneous diphtheria. Isolation is continued until at least two culture results from the nose and throat (and skin lesions, if present) taken after cessation of therapy are negative. Cutaneous wounds should be cleansed thoroughly with soap and water. Bed rest is recommended during the acute phase of the disease. The return to physical activity should be guided by the degree of toxicity and cardiac involvement. Patients with oropharyngeal or laryngeal diphtheria should be observed closely for signs of airway obstruction and aspiration. Congestive heart failure and malnutrition should be anticipated and prevented when possible.

Corticosteroid therapy is not recommended. In a study of 66 children with respiratory tract diphtheria who were alternately treated with or without prednisone for 14 days from the time of diagnosis, toxic myocarditis occurred in 26%, neuritis in 17%, and bullneck diphtheria in 10%, with no difference in occurrence or death in those who received steroids.[31] The use of digitalis for treatment of myocarditis is associated with an excess occurrence of arrhythmia.

The prognosis for diphtheria depends on the virulence of the organism, the patient's age and immunization status, the site of infection, the presence and severity of complications, and the speed of antitoxin administration. Mechanical obstruction from laryngeal or bullneck diphtheria and complications of myocarditis account for most deaths.[35] Ventricular ectopy with or without evident clinical myocarditis at the time of initiation of therapy predicted a fatal outcome with 100% sensitivity and specificity in children with severe diphtheria. A minimum case-fatality rate of 10% for respiratory tract diphtheria has not changed in 50 years, and the mortality rate was 18% and 23% in outbreaks that occurred in the 1980s and 1990s in Sweden[1] and states of the former Soviet Union,[21] respectively. The rate was 33% in a retrospective study from the United Kingdom, where deaths were observed only in people who had not been immunized.[10]

Because sustained immunity does not develop in all patients after infection, administration of diphtheria toxoid is indicated at recovery to complete the primary series or booster doses of immunization.

Management of Others

Exposed People

Public health officials should be notified promptly when a diagnosis of diphtheria is suspected or proved. Investigation is aimed at preventing secondary cases in exposed people and at determining the source case and carriers to halt spread to unexposed individuals. Reported rates of carriage in household contacts of case-patients have ranged from 0% to 25%.[9,16,36] The risk of developing diphtheria after household exposure to a case is approximately 2%; it is 0.3% after similar exposure to a carrier.

The highest priorities are prompt identification and investigation of close contacts (defined as all household contacts and those who have had intimate respiratory or habitual physical contact with the patient). The following steps should be taken for these people:

- Monitor closely for illness through the 7-day incubation period.
- Perform cultures of the nose, throat, and any cutaneous lesion.
- Give antimicrobial prophylaxis, regardless of immunization status, with oral erythromycin (40 to 50 mg/kg/day for 7 to 10 days, maximum 1 g/day). If the individual is intolerant to erythromycin or if complete adherence is not assured, intramuscular benzathine penicillin should be administered (600,000 units for those weighing <30 kg or 1,200,000 units for those weighing ≥30 kg). The efficacy of antimicrobial prophylaxis is presumed but not proved, and the newer macrolides (e.g., clarithromycin and azithromycin) have not been evaluated for their ability to eliminate carriage of *C. diphtheriae.*
- Give diphtheria toxoid vaccine doses or other suitable combination vaccine, such as – pediatric diphtheria and tetanus toxoid vaccine (DT); pediatric diphtheria and tetanus toxoids, and acellular pertussis vaccine (DTaP); tetanus toxoid, reduced diphtheria toxoid and reduced acellular pertussis vaccine (Tdap); or tetanus toxoid and reduced diphtheria toxoid vaccine (Td) – appropriate for age and prior receipt (i.e., Tdap) to immunized individuals who have not received a booster dose within 5 years. Tdap vaccine has not been evaluated in the control of outbreaks, but it should be reliable based on the immune responses elicited when it is given to people who received a primary series of DTaP.

Those who have received fewer than three doses of diphtheria toxoid or whose immunization status is unknown should be immunized with an age-appropriate preparation on a primary schedule. The use of the Schick test (intradermal injection of diphtheria toxin) to determine immunity in contacts is no longer recommended, and the reagents for testing are generally no longer available.

Asymptomatic Carriers

When an asymptomatic carrier is identified, the following steps should be taken:

- Give antimicrobial prophylaxis for 7 to 10 days.
- Give an age-appropriate preparation of diphtheria toxoid immediately if the individual has not received a booster within 5 years.[37]
- Place the individual in droplet isolation (respiratory tract colonization) or contact isolation (cutaneous colonization only) until the results of at least two subsequent cultures taken at least 24 hours apart after cessation of therapy are negative for *C. diphtheriae.*
- Perform repeat cultures at a minimum of 2 weeks after completion of therapy in cases and carriers; if the culture result is positive, an additional 10-day course of oral erythromycin should be given and follow-up cultures performed.

Neither penicillin nor erythromycin eradicates carriage in 100% of carriers. In one report[38] eradication failed in 21% of carriers after a single course of therapy. Antitoxin is not recommended for close contacts or asymptomatic carriers, even if they are inadequately immunized, because of the adverse effects of horse serum and the lack of demonstrable evidence of benefit above antimicrobial prophylaxis. Booster immunization elicits a rapid rise in antitoxin levels.

Transmission of diphtheria in modern hospitals is rare.[39] Meticulous handwashing and handling of secretions are mandatory. Only those who have had unusual contact with respiratory or oral secretions should be managed as contacts. Investigation of casual contacts of patients and carriers and of people in the community without known exposure has generally yielded extremely low carriage rates and is not recommended routinely.

Prevention

Universal immunization with vaccines containing diphtheria toxoid to provide constant protective antitoxin levels and to reduce indigenous *C. diphtheriae* is the only effective control measure. This requires multiple injections in childhood and adulthood. Serum antitoxin levels, measured by toxin neutralization tests in Vero cell culture or rabbit skin or by hemagglutination, are roughly equivalent. A concentration of 0.01 to 0.1 IU/mL is conventionally accepted as the minimum protective level, although the protective limit of antibody has not been precisely defined.[32] In outbreaks 90% of people with clinical disease have had antitoxin levels less than 0.01 IU/mL, and 92% of asymptomatic carriers have had titers greater than 0.1 IU/mL.

Vaccine Preparations

Diphtheria toxoid is prepared by formaldehyde treatment of toxin and is standardized for potency according to the specifications of the U.S. Food and Drug Administration. Toxoid is adsorbed to aluminum salts, which enhances immunogenicity. Two preparations of diphtheria toxoids are formulated according to limit of flocculation (Lf) content, a measure of quantity of toxoid. Pediatric preparations (DTP, DT, DTaP) contain 6.7 Lf units or more of diphtheria toxoid per 0.5 mL dose, whereas adolescent and adult preparations of combination vaccines of diphtheria-tetanus (Td) or tetanus–diphtheria–acellular pertussis (Tdap) contain no more than 2 Lf units of toxoid per 0.5 mL dose. The higher potency (D) formulation of toxoid is used for the primary series and for booster doses for children through 6 years of age because of superior immunogenicity and minimal reactogenicity. For individuals 7 years of age or older, Td or Tdap (for one dose only) is recommended for the primary series and booster doses because the lower concentration of diphtheria toxoid is adequately immunogenic and because increasing the content of diphtheria toxoid heightens reactogenicity with advancing age.

Schedules

For children 6 weeks through 6 years of age, five 0.5-mL doses of diphtheria-containing (D) vaccine should be given. The adult preparations (d) should not be used in children younger than 7 years because of these vaccines' reduced immunogenicity. The primary series includes doses at approximately 2, 4, and 6 months of age. The fourth dose is an integral part of the primary series and is given approximately 6 to 12 months after the third dose to maintain adequate immunity during the preschool years. A booster dose is given at 4 to 6 years (unless the fourth primary dose was administered after the fourth birthday).

For people 7 years of age or older, three 0.5-mL doses of diphtheria-containing vaccine (Td, or Tdap for one dose) are recommended as a primary series; this primary series includes two doses 4 to 8 weeks apart and a third dose 6 to 12 months after the second dose; the preferred schedule is Tdap followed by Td, but Tdap can replace any single dose of Td. The only contraindication to diphtheria toxoid is a history of neurologic or severe hypersensitivity reaction after a previous dose.

For children in whom vaccination was delayed, D or d toxoids (DT or Td) are used as follows: those who began with either diphtheria-tetanus-pertussis or DT at younger than 1 year of age should have a total of five 0.5-mL doses of D-containing vaccine by 6 years. For those beginning at or after 1 year of age, the primary series is two 0.5-mL doses of D vaccine, with a third dose 6 to 12 months later and a booster given at 4 to 6 years unless the third dose was given after the fourth birthday.[37]

A further reduction in the number of cases of diphtheria in industrialized countries will require universal booster immunization throughout life. Booster doses of 0.5 mL Td should be given every 10 years (these are conveniently given to most people at 15 years, 25 years, 35 years of age, and so forth). Tdap should be given to replace one dose of Td for routine administration. Vaccination with diphtheria toxoid should be used whenever tetanus toxoid is indicated to ensure continuing diphtheria immunity. There is no known association of DT or Td with an increased risk of convulsions. Local side effects alone do not preclude continued use. Arthus-type hypersensitivity reactions after a dose of Td have been described in adults who have received excessive doses over a short period; these reactions usually are associated with high serum levels of tetanus antitoxin. An Arthus reaction is rare in children and adolescents. DT or Td can be given concurrently with other vaccines. *Haemophilus influenzae* conjugate vaccines containing diphtheria toxoid (PRP-D) and the variant of diphtheria toxin, CRM1$_{97}$ protein (HbOC) as a carrier protein, are not substitutes for diphtheria toxoid immunization.

The author acknowledges substantial use of content contributed to previous editions by G.D. Overturf.

Key Points

Diagnosis and Management of *Corynebacterium diphtheriae* Infection

Microbiology

- Pleomorphic gram-positive bacilli
- Selective or enrichment media are required for growth.
- Infection of the bacteria with a lysogenic bacteriophage is responsible for exotoxin production.

Epidemiology

- Humans are the only reservoir.
- Infection spreads by respiratory droplets or direct contact with respiratory or skin secretions.
- As a result of universal childhood immunization, diphtheria cases in the U.S. are imported; however, diphtheria is still endemic in many developing countries.
- Classic presentations include pharyngitis and cutaneous

diphtheria, but endocarditis and arthritis have been documented.

- Complications include toxic cardiomyopathy and neuropathy.

Diagnosis

- Isolation from the nasopharynx or from skin lesions
- Coryneform bacteria isolated from the blood of patients suspected of having diphtheria should not be discounted as contaminants before identification to the species level.
- PCR (not commercially available) allows detection of regulatory gene for toxin production.

Treatment

- Specific antitoxin is lifesaving if administered within 24 hours of symptom onset.
- Equine antitoxin is available in the U.S. only through the CDC Emergency Operations Center.
- Antimicrobial therapy is indicated to limit toxin production and prevent transmission.
- Strains usually are susceptible to penicillins and macrolides.
- Administration of diphtheria toxoid vaccine is indicated upon recovery because not all patients develop sustained immunity after infection.

Infection Control/Prevention

- Droplet isolation is indicated for pharyngeal and contact isolation for cutaneous diphtheria cases.
- The only effective control measure is universal immunization with vaccines containing diphtheria toxoid and booster doses throughout life.

Other Corynebacteria

Denise F. Bratcher

Corynebacterium species, which are recognized as members of the normal human flora, are isolated from the skin, mucous membranes, and gastrointestinal tract. Although frequently dismissed as contaminants in clinical specimens, corynebacteria are recognized more often as pathogens, particularly in immunocompromised people.[1,2] Infections caused by *Corynebacterium* species have occurred predominantly among patients with prosthetic and other medical devices. Currently, 88 valid studies have been published on *Corynebacterium* species, and further definition of the pathogenic role of these species in human infections and of the mechanisms of pathogenesis continues to be elucidated. Many case reports have questionable validity because of the limitations of commercial identification systems, use of inappropriate identification methods, significant changes in taxonomy, and lack of distinction between colonization and infection.[1]

Identification of significant clinical isolates of *Corynebacterium* spp. and antimicrobial susceptibility and synergy testing are warranted; identification is enhanced by the combination of biochemical testing using commercially available panels, sequence-based methods using 16S (small subunit) ribosomal RNA (rRNA) gene sequencing, and matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry.[3] Characteristics of reported infections caused by *Corynebacterium* species are outlined in Table 131.1. *Corynebacterium* infections among children rarely cause severe symptoms or mortality.[4]

TABLE 131.1

Characteristics of Infection and Habitats of Frequently Reported *Corynebacterium* Species

	Infection			
Species	**Normal Flora**	**Normal Host**	**Compromised Host**[a]	**Children**
C. afermentans	Human Animal	Brain abscess Hepatic abscess	BSI Endocarditis Pulmonary infections	
C. amycolatum		Septic arthritis Endocarditis	BSI Endocarditis Peritonitis	BSI
C. bovis	Animal	Skin infection Meningitis Mastoiditis	BSI Endocarditis Glomerulonephritis Meningitis Septic arthritis	
C. coyleae			Ascites Sepsis Skin/soft tissue infection	BSI
C. glucuronolyticum	Human Animal		Prostatitis Genitourinary infections	
C. jeikeium	Human	BSI Cardiac device infections Otitis media Septic arthritis	Abscess BSI Endocarditis Enteritis Meningitis Osteomyelitis Peritonitis Pneumonia Pyelonephritis Septic arthritis Skin infections Transverse myelitis Urinary tract infection Ventriculitis	Abscess BSI Endocarditis Meningitis Pulmonary infection
C. macginleyi			Catheter-related infection Conjunctivitis Endocarditis Endophthalmitis Keratitis Sepsis Urinary tract infection	S: Multiple V: FQ R: Ery

C. minutissimum[d]	Human	BSI Cellulitis Erythrasma (polymicrobial) Meningitis	BSI Abscess Endocarditis Erythrasma Peritonitis	Erythrasma Pyelonephritis
C. propinquum	Human	Endocarditis	Pulmonary infection	Endocarditis
C. pseudodiphtheriticum (Corynebacterium hofmannii)	Human	Conjunctivitis/keratitis Discitis Endocarditis Lymphadenitis Pharyngitis (membranous) Pulmonary infections Skin infections	BSI Endocarditis Peritonitis Pulmonary infections Septic arthritis Surgical site infection Urinary tract infection[d]	BSI Endocarditis Lymphadenitis Otitis media Pharyngitis (membranous) Pulmonary infections Surgical site infection Urinary tract infection
C. pseudotuberculosis (Corynebacterium ovis)	Animal	Lymphadenitis Pneumonia	Abscess Lymphadenitis Pneumonia	Lymphadenitis Septic arthritis
C. striatum[d]	Human		Endocarditis BSI Central line infection Chorioamnionitis Meningitis Osteomyelitis Peritonitis Pulmonary infections Septic arthritis Skin/soft tissue infection	BSI Ventriculitis

C. xerosis[d]	Human	Endocarditis	BSI Central nervous system infections	BSI Endocarditis Meningitis

			Endocarditis Keratitis (postoperative) Osteomyelitis Peritonitis Pulmonary infections Septic arthritis	Pericarditis Ventriculitis

[a] Compromised hosts include immunodeficient patients, neutropenic patients, those with indwelling devices, and postsurgery and trauma patients.

[b] There are no reports of controlled clinical trials using different antimicrobial agents in the treatment of infections with *Corynebacterium* species. Notation is based on antimicrobial susceptibilities reported in cases and laboratory evaluations.

[c] MDR: Multidrug resistance has been reported; the only drugs active against these strains are glycopeptides, linezolid, quinupristin/dalfopristin, daptomycin, and tigecycline.

[d] Some reports likely represent misidentification of *Corynebacterium amycolatum* or another *Corynebacterium* strain.[1]

[e] Surgical excision after parenteral antibiotic therapy is necessary for cure.

BSI, bloodstream infection; Amg, aminoglycosides; Ceph, cephalosporins; 1G Ceph, first-generation cephalosporins; 2G Ceph, second-generation cephalosporins; 3G Ceph, third-generation cephalosporins; Chloro, chloramphenicol; Clin, clindamycin; Dapto, daptomycin; Ery, erythromycin; Imip, imipenem; Lin, linezolid; Pcn, penicillin; FQ, fluoroquinolones; R, resistant; Rif, rifampin; S, susceptible; Teico, teicoplanin; Tet, tetracyclines; Tig, tigecycline; T/S, trimethoprim-sulfamethoxazole; V, variable; Vanc, vancomycin.

Corynebacterium Jeikeium

Corynebacterium jeikeium, formerly known as Centers for Disease Control and Prevention (CDC) group JK, was identified as a distinct group in 1976, and a pathogenic role in endocarditis after cardiovascular surgery has been noted since 1963. *C. jeikeium* increasingly has been identified in association with a variety of clinical entities, predominantly in immunocompromised people, and it is recognized as a significant nosocomial pathogen. *C. jeikeium* is the most frequently recovered medically significant corynebacterial species in patients in intensive care units.[5]

Only pathogenic for humans, *C. jeikeium* is found in soil and water and is part of normal human skin flora. The colonization rate increases with hospitalization; it has been reported in hospital personnel and in up to 40% of hospitalized patients, especially on the skin of the perirectal area, groin, and axilla.[6] Infection is thought to occur when *C. jeikeium* invades through mucosal breaks and colonizes prosthetic devices. Risk factors for *C. jeikeium* infection include prolonged hospitalization; profound, extended granulocytopenia; multiple or prolonged courses of antibiotic therapy; disruption of mucocutaneous barriers; and presence of a medical device.

In one study *C. jeikeium* was recognized as the most frequent cause of bloodstream infection (BSI) among patients who had received a bone marrow transplant[6]; BSI also has been reported among immunocompetent and immunosuppressed patients. *C. jeikeium* is the most common cause of diphtheroid endocarditis of prosthetic valves,[7] and it also can infect native valves. *C. jeikeium* infection is the corynebacteria infection most likely to require valve replacement.[8] Other infections attributed to *C. jeikeium* include skin and wound infections, catheter-related infection, enteritis, meningitis, osteomyelitis, peritonitis, pneumonia, prosthetic joint infection, pyelonephritis, and liver abscess in a patient with AIDS.[9–17] Several infections caused by *C. jeikeium* have been reported in children, including meningitis associated with a ventriculoperitoneal shunt, BSI, endocarditis, and a localized skin abscess at a puncture site.[18–20] Most cases were associated with immunosuppression, a medical device, or trauma.

C. jeikeium is a nonmotile, gram-positive bacillus that can appear to be coccobacillary. Growth appears as discrete, pinpoint, smooth white colonies that take on a characteristic metallic sheen after 24 to 48 hours of incubation. The bacterium ferments glucose but does not produce urease or reduce nitrate. Identification frequently is confirmed on the basis of resistance to many antibiotics, including β-lactams, aminoglycosides, erythromycin, and tetracycline. Vancomycin generally is the most active antibiotic against *C. jeikeium* and is the drug of choice for the treatment of these infections, although vancomycin resistance has been reported.[21] Telithromycin, linezolid, and quinupristin/dalfopristin have good in vitro activity.[22] Although some have suggested that removal of a central venous catheter may not always be necessary, removal of involved prosthetic devices usually is required for cure. *Corynebacterium* species form biofilms that are refractory to vancomycin therapy.[6,23] Prevention of nosocomial transmission of *C. jeikeium* depends on meticulous handwashing and aseptic technique. Further elucidation of the modes of transfer of *C. jeikeium* in healthcare settings may suggest additional methods of infection control.

Other *Corynebacterium* Species

The frequency of corynebacteria infections has been increasing over the past 20 years; in addition, many new *Corynebacterium* species have been established, and more new identifications are expected.[1] Corynebacteria are diverse morphologically, metabolically, and structurally. Multiple changes and improvements in the taxonomic framework for coryneform bacteria have facilitated clinical associations.

C. amycolatum, a species established in 1988, probably accounted for many previously reported infections that had been misidentified as *C. kutscheri, C. minutissimum, C. striatum,* and *C. xerosis.*[1] *C. amycolatum,* one of the species most commonly isolated from clinical specimens,[1] has been reported as a cause of septicemia in a patient with diabetes[24] and a premature infant,[25] and also as a cause of pyogenic arthritis.[26] *C. amycolatum* typically is resistant to multiple antibiotics but is susceptible to vancomycin and teicoplanin.

Other newly identified *Corynebacterium* spp. have been reported in association with human disease in rare cases; these include *C. accolens, C. afermentans, C. argentoratense, C. auris, C. falsenii, C. glucuronolyticum, C. kroppenstedtii, C. lipophiloflavum, C. macginleyi, C. propinquum, C. resistens, C. riegelli, C. simulans, C. tuberculostearicum,* and *C. ureicelerivorans.*[27–30]

Current methods of identification of *Corynebacterium* species, especially those relying on commercial identification systems, may be inadequate because a limited number of species are represented. Similarly, numerous differences within reference strains of *Corynebacterium* species have been noted.[1] Referral of isolates to a reference laboratory may be necessary. Standardized guidelines for susceptibility testing of *Corynebacterium* species were updated in 2010 and 2012.[31,32] Variable susceptibility to antimicrobial agents mandates specific testing of each clinical isolate. In general, *Corynebacterium* species are susceptible to vancomycin and linezolid.[3] Vancomycin is recommended for empiric therapy of suspected *Corynebacterium* infections. Multidrug-resistant strains have been identified, primarily *C. jeikeium*, *C. striatum*, and *C. urealyticum*.

Key Points

Corynebacterium Species

- *Corynebacterium* species often are dismissed as contaminants in clinical specimens; however, they increasingly are recognized as pathogens, especially in immunocompromised people.

- Newer molecular and protein fingerprinting methods of identification have led to clarification of the taxonomy of *Corynebacterium* species and have corrected some previous, misleading reports.

- *Corynebacterium* species have been associated with a variety of infections; the propensity for certain infections varies by species.

- Variable susceptibility of corynebacteria to antimicrobial agents, including some multidrug-resistant strains, requires specific susceptibility testing of each isolate.

Listeria monocytogenes

Monica M. Farley

The bacterium *Listeria monocytogenes* is a rare but important cause of severe illness in neonates, pregnant women, older adults, and people with impaired cell-mediated immunity. It often presents as a life-threatening bloodstream infection (BSI) and meningoencephalitis or as less severe febrile gastroenteritis.[1,2] It has been established as a foodborne pathogen associated with both sporadic and outbreak-related disease, raising concerns about food safety and earning *L. monocytogenes* infection recognition as one of the most lethal foodborne diseases.[3]

Description of the Pathogen

L. monocytogenes is a facultatively anaerobic, nonsporulating, catalase-positive, oxidase-negative, short, nonbranching gram-positive bacillus that grows readily on blood agar, producing incomplete β-hemolysis.[4,5] The bacterium has polar flagellae and exhibits a characteristic tumbling motility at 25°C. Unlike most bacteria, *L. monocytogenes* grows well at refrigerator temperature (4°C to 10°C), and by so-called cold enrichment, it can be separated from other contaminating bacteria by long incubation in this temperature range. Selective media have been developed to isolate the organism from specimens containing multiple species (food, stool) that appear to be superior to cold enrichment.[4,6]

In clinical specimens the organisms can be gram variable and can resemble diphtheroids, cocci, or diplococci. The media typically used to isolate bacteria that cause diarrhea from stool cultures inhibit listerial growth. Laboratory misidentification of the organisms as diphtheroids, streptococci, or enterococci is not uncommon; therefore, isolation of a "diphtheroid" from blood or cerebrospinal fluid (CSF) should always alert the clinician to the possibility that the organism actually is *L. monocytogenes.*[7,8]

Of the six *Listeria* species (*L. monocytogenes, L. seeligeri, L. welshimeri, L. innocua, L. ivanovii,* and *L. grayi*), only *L. monocytogenes* is pathogenic for humans. *L. monocytogenes* has at least 13 serovars, but almost all disease is caused by types 4b, 1/2a, and 1/2b.[3,9] A number of molecular techniques, including pulsed-field gel electrophoresis, ribotyping, multilocus enzyme electrophoresis and, most recently, whole-genome sequencing (WGS) analysis by whole-genome multilocus sequence typing, have been used to categorize isolates into distinct groups and have proved useful for investigating epidemics.[10–15]

Epidemiology

L. monocytogenes is an important cause of zoonoses, especially in herd animals. Widespread in nature, it commonly is found in soil, decaying vegetation, and as part of the fecal flora of many mammals.[4,9] The organism also has been isolated from the stool of approximately 5% of adults,[9,16] and higher rates of recovery have been reported from household contacts of patients with clinical infection.[17] In three healthy, asymptomatic adults who were followed for 1 year, *L. monocytogenes* was present transiently in 3.5% of stool specimens.[18]

Many foods are contaminated with *L. monocytogenes,* and recovery rates of 15% to 70% and higher are common from raw fruits and vegetables, raw milk, fish, poultry, and meat, including fresh or processed chicken and beef available as ready-to-eat products at supermarkets and delicatessen (deli) counters.[5] Although disease is rare, ingestion of *L. monocytogenes* must be a common occurrence.

Two active surveillance studies performed in the 1980s by the

Centers for Disease Control and Prevention (CDC) indicated annual infection rates of 0.74 cases per 100,000 population, accounting for approximately 1850 cases a year in the United States and 425 deaths.[19] Listeriosis declined significantly over the next two decades, after food industry regulations were instituted to minimize the risk of foodborne listeriosis. Surveillance reports from 2009 to 2011 showed a low but stable incidence rate of 0.29 cases per 100,000 population.[20–22] The highest infection rates are seen among older adults, people who are immunocompromised, pregnant women, and newborns (Fig. 132.1).[12,19,21] In a report that summarized data from U.S. listeriosis cases and outbreaks between 2009 to 2011, pregnancy-associated disease (maternal and fetal/newborn) accounted for 14% of all cases, and the risk was highest among pregnant women of Hispanic ethnicity.[21] Compared with the general population, the rate was 4-fold higher for adults 65 years or older, 10-fold higher for pregnant women, and 24-fold higher for pregnant Hispanic women.[21]

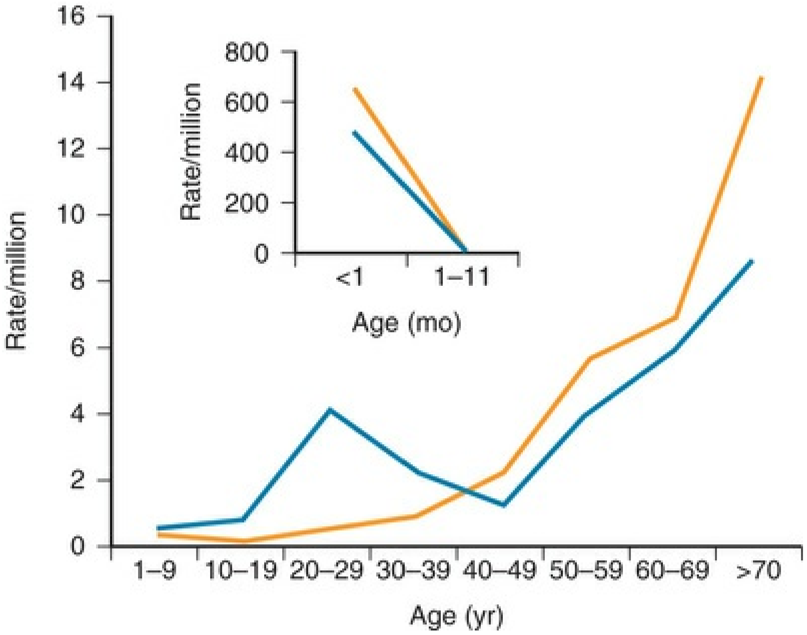

FIGURE 132.1 Age-specific incidence of listeriosis by gender. The *orange line* indicates male patients; the *blue line* indicates female patients. (Redrawn from Ciesielski CA, Hightower AW, Parsons SK, et al. Listeriosis in the United States: 1980–1982. Arch Intern Med 1988;148:1416–1419.)

Most cases that are not associated with pregnancy (≥70%) occur in individuals with one or more underlying conditions, including malignancy, diabetes mellitus, renal failure, AIDS, organ transplantation, and cirrhosis, and in patients receiving immunosuppressive agents, including corticosteroids and biologic immune modulators used in immunologic or inflammatory diseases.[23]

Listeria was recognized as a foodborne pathogen after a 1983 report described a foodborne outbreak of human listerial infection in Canada that was linked convincingly to contaminated coleslaw.[16] Many subsequent foodborne outbreaks resulting in invasive disease (BSI, meningitis) have been documented[12,24]; vehicles have included milk,[25] soft cheeses,[26,27] ice cream,[28] cantaloupes,[21] stone fruit,[14] prepackaged caramel apples,[29] sprouts, ready-to-eat seafood, pork products,[30] hot dogs, and deli-ready turkey.[31,32] *L. monocytogenes* can persist in food processing environments and contribute to ongoing food contamination.[33] Substantial economic losses have occurred from major food recalls prompted by outbreaks and/or detection of *Listeria* in food commodities. The importance of food as a source of sporadic listeriosis was illustrated by two CDC studies, which showed that 11% of all refrigerator food samples were contaminated with *Listeria*; 64% of infected patients had at least one food item in their refrigerator that was contaminated; and in 33% of cases, isolates from the patient and from a contaminated food were identical strains.[34,35]

Although most cases of human listeriosis appear to be foodborne, other modes of transmission are possible, such as transmission from mother to child transplacentally or through an infected birth canal, and cross infection in neonatal nurseries.[36,37] A common-source outbreak was traced to contaminated mineral oil used for bathing infants.[38] Localized cutaneous infections have occurred in veterinarians and farmers after direct contact with aborted calves and infected poultry. *L. monocytogenes* has been isolated from units of donated apheresis platelets on multiple occasions, but no contaminated units have been transfused.[39,40]

In 1998 the CDC added *L. monocytogenes* to PulseNet (http://www.cdc.gov/pulsenet/), a network of public health and food regulatory laboratories that use pulsed-field gel electrophoresis to subtype foodborne pathogens so as to speed detection of disease clusters that may have a common source.[41] This system has been used effectively for the early detection of outbreaks of listeriosis.[12,42] Future monitoring may rely on methods involving whole-genome sequencing.[14,15]

Pathogenesis

Except for vertical transmission from mother to fetus and rare instances of cross contamination in the delivery suite or neonatal nursery, human-to-human infection has not been documented.

Most often, listeriae are acquired through ingestion of contaminated food.[2,5,12] The oral inoculum required to produce clinical infection has not been not well established yet, but infectious doses in animal experiments have ranged from 10^4 to 10^9 organisms.[43,44] The infectious dose may be lower in people who are immunocompromised and in those with reduced gastric acid production because of the use of antacids, histamine-2 (H_2) blocking agents, proton pump inhibitors, or ulcer surgery.[45,46] The incubation period appears to be shorter than the previously accepted 31 days[26] and varies by clinical syndrome. A careful analysis of 37 *Listeria* cases with precise incubation periods, reported over a 32-year period, demonstrated the following incubation periods: overall incubation period for all invasive listeriosis, 8 days (range, 1 to 67 days); pregnancy-associated disease, 27 days (range, 17 to 67 days); BSI, 2 days (range, 1 to 12 days); and central nervous system (CNS) infection, 9 days (range, 1 to 14 days). The median incubation period for gastroenteritis was much shorter (mean, 24 hours; range, 6 to 240 hours).[47] Although not required for *L. monocytogenes* infection, intercurrent gastrointestinal infection with another pathogen may enhance invasion in people colonized with *L. monocytogenes*.[48,49] Both meningitis and BSIs caused by *Listeria* have occurred shortly after colonoscopy and sigmoidoscopy.[50,51]

After ingestion of *L. monocytogenes,* bacteria can colonize the intestine or cross the intestinal epithelium via transcytosis and invade mesenteric lymph nodes and the blood.[5,52,53] The liver and spleen are target organs that may serve as reservoirs of persistent organisms.[53] Once the bacteria are in the bloodstream, dissemination can occur to any site; *L. monocytogenes* has a particular predilection for the CNS and the placenta. It is generally believed that listeriae reach the CNS by a bacteremic route, but animal experiments suggest that rhombencephalitis can develop by intra-axonal spread of bacteria from peripheral sites to the CNS.[54] The intracellular, molecular pathogenesis of listeriosis has been reviewed in detail.[53,55–57] Several virulence factors enable *L. monocytogenes* to thrive as an intracellular organism. The listerial surface proteins internalin A and internalin B (InlA and InlB) aid adherence to cell surface receptors, including[58] E-cadherin, a receptor on macrophages and intestinal epithelial cells, to promote entry of the organism into the host cell.[52,53,59,60] A major virulence factor, pore-forming listeriolysin O, along with phospholipases, enables listeriae to escape from the phagosome and avoid intracellular killing.[61] Once free in the cytoplasm, the bacterium can divide and, by inducing host cell actin polymerization, propel itself to the cell membrane,[53,62] where pseudopod-like projections enable invasion of adjacent host cells (Fig. 132.2). The bacterial surface protein ActA is necessary to induce actin filament assembly into a cometlike tail that promotes cell-to-cell spread, thus maintaining an intracellular life cycle to evade the host immune response. *Listeria* organisms have a variety of mechanisms that facilitate iron acquisition, transport, and metabolism.[5,63] In vitro, iron enhances organism growth; in animal models of listerial infection, iron overload is associated with enhanced susceptibility to infection and iron supplementation with enhanced lethality, whereas iron depletion results in prolonged survival.[64] The clinical associations of listerial infection with hemochromatosis[8] and of outbreaks in dialysis patients with transfusion-induced iron overload[65] attest to the importance of iron in the pathogenesis of listeriosis.

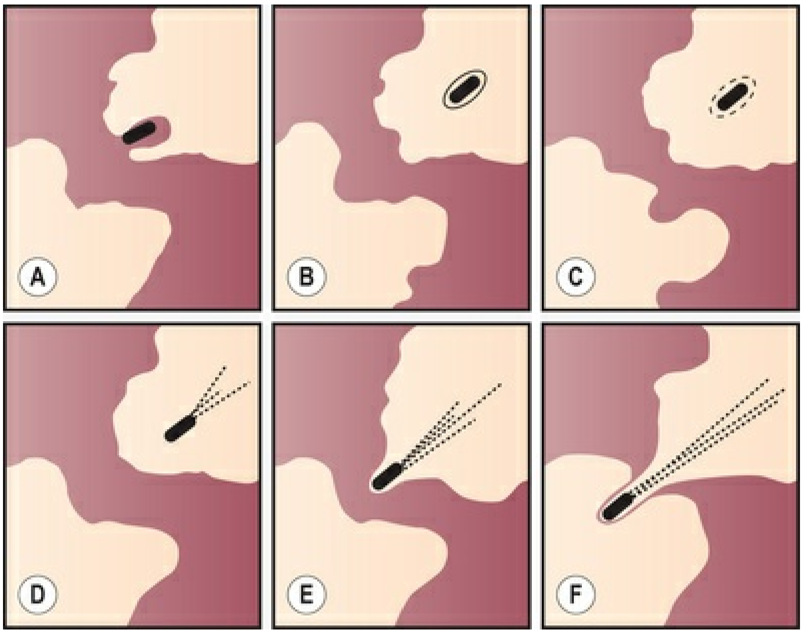

FIGURE 132.2 Steps in the engulfment of *Listeria monocytogenes* and subsequent transfer of the bacterium from one macrophage to another. (A) Adjacent macrophages, one of which has been induced to phagocytose *L. monocytogenes*. (B) After ingestion the organism is held in a single membrane phagosome. (C) Through the action of listeriolysin O, the bacterium escapes from the phagocytic vacuole before it is damaged and replication occurs. (D) Host cell actin is induced by the organism, now free in the cytoplasm. (E) Polymerized actin forms an elongating lattice that propels the bacterium to the host cell membrane, forming a pseudopod-like extension. (F) The pseudopod-like extension containing a bacterium is engulfed by an adjacent macrophage, resulting in a double-membrane vacuole. (Drawing by B. Lorber.)

Immunity

Resistance to listerial infection involves both innate and adaptive immune responses.[66] The adaptive response primarily is cell mediated, as evidenced by experiments showing that immunity can be transferred by sensitized lymphocytes but not by antibodies.[67] Further evidence is provided by the overwhelming clinical association between listerial infection and conditions of impaired cellular immunity, including lymphoma, pregnancy, AIDS, and corticosteroid immunosuppression.[1,2,7,8,68–70] Invasive listeriosis has complicated the use of agents that neutralize tumor necrosis factor-α (e.g., infliximab) in a variety of conditions.[71–75] In a murine model, tumor necrosis factor was found to play a critical role in the intracerebral control of *L. monocytogenes* infection.[76] Toll-like receptor 2 contributes to the recognition and control of listeriosis.[77] The role of humoral immunity is unknown, although both immunoglobulin M (absent at birth) and classical complement activity (low in neonates) have been shown to be necessary for efficient opsonization of *L. monocytogenes.*[78]

Listeriosis has been reported to be 100 to 1000 times more common in patients with AIDS compared with the general population.[79–82] However, listerial infection rates have declined as a result of effective antiretroviral therapy with immune reconstitution and the use of trimethoprim-sulfamethoxazole (TMP-SMX) for prophylaxis against *Pneumocystis jirovecii* pneumonia.[22,83] The frequency of listeriosis is not increased in people with neutrophil deficiencies in number or function, splenectomy, persistent complement deficiency, or immunoglobulin disorders; the latter finding is not surprising because of the cell-to-cell spread of *L. monocytogenes* and the predominant intracellular location.

Clinical Syndromes

The species name derives from the fact that an extract of the *L. monocytogenes* cell membrane has potent monocytosis-producing activity in rabbits; however, monocytosis is an uncommon feature of human infection.[84,85]

Infection in Pregnancy.

During gestation, mild impairment of cell-mediated immunity occurs, and pregnant women have at least a 10-fold increased risk of developing listerial BSI.[21,86,87] Listeriae can proliferate in the placenta, which serves as a sanctuary site that is not subject to the usual defense mechanisms, and cell-to-cell spread facilitates maternal-fetal transmission.[88,89] Listeriosis in pregnant women can be asymptomatic; can result in mild symptoms, including gastroenteritis or flulike symptoms; or can result in overt sepsis. CNS infection, the most commonly recognized form of listeriosis in other groups, is rare during pregnancy in the absence of other risk factors.[1,16,19] BSI manifests clinically as an acute febrile illness, often accompanied by myalgia, arthralgia, headache, and backache. Maternal mortality is uncommon. Infection can occur at any time during pregnancy but is most common in the third trimester, probably because of the major decline in cell-mediated immunity seen at 26 to 30 weeks of gestation.[86]

Neonatal Infection.

Despite relatively mild and often self-limited maternal disease manifestations, the impact on the fetus can be devastating. Between 20% and 33% of pregnancy-related infections result in fetal loss from stillbirth or spontaneous abortion. The risk of fetal/neonatal loss is significantly greater with earlier gestational age at the time of onset of listeriosis; when *Listeria* is isolated from the mother's blood; and with a history of symptomatic maternal infection.[90–92] Prompt diagnosis and antimicrobial therapy can result in the birth of a healthy infant.[93,94] The fetus can be stillborn or can die within hours as a result of a disseminated form of listerial infection known as granulomatosis infantiseptica, which is characterized by widespread microabscesses and granulomas that are particularly prevalent in the liver and spleen. With this infection, abundant bacteria often are visible on a Gram stain of the meconium.[95–97]

Most pregnancy-associated *Listeria* cases result in live births. Neonatal infection manifests similarly to group B streptococcal disease in one of two forms[2]: (1) early onset sepsis syndrome, most often occurring in the first 48 hours after birth, usually associated with prematurity, and probably acquired in utero; or (2) late onset meningitis, occurring at about 2 weeks of age in term infants, who most likely acquired organisms from the maternal vagina at parturition.[38]

In early onset disease, *L. monocytogenes* can be isolated from the conjunctivae, external ear, nose, throat, meconium, amniotic fluid, placenta, and blood and sometimes from the CSF. A Gram stain of meconium may show gram-positive rods, allowing early diagnosis. The highest concentrations of bacteria are found in the neonatal lung and gut, which suggests that infection may be acquired in utero from infected amniotic fluid rather than by a hematogenous route.[98] In rare cases, purulent conjunctivitis and a disseminated papular rash have been described in neonates with early onset disease, but clinical infection is otherwise similar to infections caused by other bacterial pathogens.

Bloodstream Infection.

Bacteremia without an evident focus is the most common manifestation of listeriosis after the neonatal period.[1,2,12] Clinical manifestations typically include fever and myalgias; a prodromal illness with nausea and diarrhea can occur.

Meningitis.

An active surveillance study of bacterial meningitis from 2003 to 2007 showed that *L. monocytogenes* accounted for 5% of cases in neonates and 9% of those in people 65 years of age or older; this represented an overall decline of 46% and 36%, respectively, compared with earlier meningitis surveillance studies.[83,99] Worldwide, *L. monocytogenes* is one of the three major causes of neonatal meningitis, and it remains an important cause of bacterial meningitis in older adults, particularly those with malignancies or organ transplants, and those receiving immunosuppressive therapy for any reason.[2,83,100–102]

Clinically, meningitis caused by *L. monocytogenes* generally is similar to meningitis from more common causes.[103] However, *L. monocytogenes* has tropism for the brain parenchyma (particularly the brainstem) and the meninges.[2,8] Many patients with meningitis experience altered consciousness, seizures, or movement disorders and actually have meningoencephalitis. Features particular to listerial meningitis are summarized in Table 132.1.

TABLE 132.1

Distinctive Features of Listerial Meningitis Compared with Those of More Common Bacterial Etiologies

Feature	Rate of Occurrence (%)
CLINICAL AND LABORATORY	
Subacute presentation (>24 hr) is more common	~60
Unimpaired neck movement is more common	25
Movement disorders (ataxia, tremors, myoclonus) are more common	15–20
Seizures are more common	~25
Fluctuating mental status is common	~75
Focal neurologic findings are more common	35–40
Positive blood culture result is more common	63–75
CEREBROSPINAL FLUID (CSF)	

Positive Gram stain result is less common	30–40
Normal CSF glucose level is more common	>60
Mononuclear cell predominance is more common	~30

In several studies of *L. monocytogenes* meningitis in adults,[104,105] notable clinical features included headache (67% to 88%), nausea or vomiting (46% to 83%), and fever (90% to 91%); however, only 70% to 75% of patients had a stiff neck at the time of presentation. A focal neurologic deficit was present in 32% to 37% (likely reflecting the organism's propensity for brain parenchymal involvement). Just under one half (43% to 49%) had the classic meningitis triad of fever, neck stiffness, and change in mental status. In one study[104] 19 of 30 patients had experienced symptoms for longer than 24 hours at presentation, and 8 had symptoms for 4 days or longer. In another study, the median duration of symptoms at the time of presentation was 70 hours.[105] Remarkable CSF findings included a median white blood cell count of 550 to 620 cells/mL (range, 24 to 16,003 cells/mL) and a protein level of 252 mg/dL. Gram stain of CSF revealed a gram-positive rod in only 28% to 30% of patients, and blood cultures were positive in 46% to 63% of patients. Sixteen percent of survivors had sequelae at discharge, including hemiparesis and cranial nerve palsies; the mortality rate was 15% to 28%.[104,105]

Brainstem Encephalitis (Rhombencephalitis).

An unusual form of listerial encephalitis involves the brainstem[106] and is similar to the unique zoonotic listerial infection known as circling disease of sheep.[107] In contrast to other listerial CNS infections, this illness usually occurs in healthy older children and adults; neonatal cases have not been reported. The typical clinical picture is a biphasic illness with a prodrome of fever, headache, nausea, and vomiting lasting about 4 days, followed by the abrupt onset of asymmetric cranial nerve deficit, cerebellar signs, and hemiparesis or hemisensory deficit, or both. Respiratory failure develops in about 40% of cases, and nuchal rigidity is present in about 50%. The CSF is only mildly abnormal, and the CSF culture result is positive in about one third of cases; almost two thirds are bacteremic. Magnetic resonance imaging is superior to computed tomography for demonstrating rhombencephalitis.[106,108] Mortality is high, and serious sequelae are common in survivors.

Brain Abscess.

Macroscopic brain abscesses account for about 10% of CNS listerial infections. Bacteremia is almost always present, and concomitant meningitis, with isolation of *L. monocytogenes* from the CSF, is found in 25% of cases; both of these features are rare in other forms of bacterial brain abscess.[109] About 50% of cases occur in groups known to be at risk for listerial infection. Subcortical abscesses in the thalamus, pons, and medulla are common; localization in these sites is exceedingly rare when abscesses are caused by other bacteria. Mortality is high, and survivors usually have serious sequelae.[110]

Endocarditis.

Listerial endocarditis accounts for about 6% to 7.5% of adult listerial infections.[8,111] It affects the population at risk for viridans streptococcal endocarditis, produces both native valve and prosthetic valve disease, and has a high rate of septic complications; the mortality rate is 48%.[112,113] Cases in children are rare.

Localized Infection.

Rare reports of focal infections from which *L. monocytogenes* has been isolated include direct inoculation resulting in conjunctivitis,[114] skin infection,[115] and lymphadenitis.[8] BSI can lead to hepatic infection,[116,117] cholecystitis,[118,119] peritonitis,[120,121] splenic abscess,[9] pleuropulmonary infection,[122–124] septic arthritis (and often prosthetic joint infections later),[125,126] osteomyelitis,[127] pericarditis,[128] myocarditis,[129] infected aortic aneurysm,[130,131] and endophthalmitis/panophthalmitis.[8,132] Complications, including disseminated intravascular coagulation,[133] adult respiratory distress syndrome,[134] and rhabdomyolysis with acute renal failure,[135] have been documented. Nothing clinically unique distinguishes these localized infections; many, but not all, have occurred in people known to be at risk for listeriosis.

Febrile Gastroenteritis.

Patients with invasive listeriosis can have a history of antecedent gastrointestinal illness, often accompanied by fever. Although sporadic cases of gastrointestinal illness caused by *L. monocytogenes* appear to be rare,[136] multiple outbreaks of foodborne gastroenteritis caused by the organism have been documented.[137] In a particularly large outbreak involving two schools, 1566 individuals, most of them children between the ages of 6 and 10, became ill after eating cafeteria food provided by caterers; 19% were hospitalized.[138] Illness typically occurs 24 hours (range, 6 hours to 10 days) after ingestion of a large inoculum of bacteria and usually lasts 1 to 3 days (range, 1 to 7 days); attack rates are high (52% to 100%) and often involve healthy individuals. Common symptoms include fever, watery diarrhea, nausea, headache, and pains in joints and muscles. Vehicles of infection have included chocolate milk, cold corn and tuna salad, cold smoked trout, jellied pork, and deli meat. *L. monocytogenes* should be considered a possible etiology in outbreaks of febrile gastroenteritis when routine cultures fail to yield a pathogen.

Diagnosis

Diagnosis requires isolation of *L. monocytogenes* from clinical specimens (e.g., CSF, blood) and identification of the organism through standard microbiologic techniques. Antibodies to listeriolysin O have not proved useful in invasive disease,[139] nor have polymerase chain reaction probes.[140] Antibodies to listeriolysin O may be useful during investigations of outbreaks of febrile gastroenteritis.[141] Selective media are required to isolate *Listeria* from stool specimens, and use of such media should be considered in an outbreak of febrile gastroenteritis when the results of routine stool cultures are negative.[142] MRI is superior to CT for demonstrating parenchymal brain involvement, especially in the brainstem.[106,108]

Treatment

No controlled trials have established a drug of choice or duration of therapy for listerial infection. Ampicillin generally is considered the preferred agent.[8,143–146] Based on the synergy seen in vitro and in animal models,[147] many authorities suggest adding gentamicin to ampicillin for treatment of BSI in patients with significant immunocompromising conditions, particularly in cases of meningitis and endocarditis.[144] However, clinical evidence for an improved outcome with the addition of aminoglycosides, gathered from observational studies of listeriosis in adults who were not pregnant, is inconclusive.[148] In one nonrandomized study,[149] the combination of TMP-SMX plus ampicillin was associated with a lower failure rate and fewer neurologic sequelae than ampicillin combined with an aminoglycoside.

TMP-SMX is the best alternative for patients intolerant of penicillins.[144,150–152] In rare cases, oral TMP-SMX has been used effectively.[153] Meropenem has been suggested as an alternative treatment for *Listeria* meningitis.[154] No currently available cephalosporin should be used because none has adequate activity,[144,155] and meningitis has developed in patients receiving cephalosporins.[156] For this reason, ampicillin always is included in empiric therapy for septicemia or meningitis in infants younger than 2 months of age, and it is recommended for empiric coverage of bacterial meningitis in pregnant women, adults with immunocompromising conditions, and people older than 50 years of age.[154]

Vancomycin has been used successfully in a few patients with penicillin allergy,[157,158] but other patients have developed listerial meningitis while receiving vancomycin.[159] Rifampin is active in vitro; however, clinical experience is minimal, and in animal models the addition of rifampin to ampicillin was not more effective than was ampicillin used alone.[145] Although fluoroquinolones and linezolid show good in vitro activity, clinical experience is mixed,[160–162] and to date too limited to support recommending these agents for therapy.

With listerial infections, initial dosing of antibiotics as for meningitis is prudent for all patients, even in the absence of CNS or CSF abnormalities, because of the high affinity of *L. monocytogenes* for the CNS. Patients with listerial meningitis should be treated for no fewer than 3 weeks; bacteremic patients without CSF abnormalities can be treated for 2 weeks.

No data are available on antimicrobial efficacy in listerial gastroenteritis. The illness generally is self-limited, but secondary meningitis that developed 19 days after febrile gastroenteritis has been reported in a 72-year-old adult[163]; this suggests that treatment may be prudent in a patient at high risk for invasive listeriosis.

Extracorporeal membrane oxygenation has been used with some success in neonates with severe *L. monocytogenes* disease.[164]

Prevention

Recommendations for prevention of listeriosis from a foodborne source are presented in Box 132.1.[165–167]

Box 132.1

Dietary Recommendations for Preventing Foodborne Listeriosis

For All People

1. Rinse raw produce (e.g., fruits and vegetables) thoroughly under tap water before preparing
2. Scrub firm produce (e.g., melons and cucumbers) with a clean brush
3. Keep uncooked meats separate from vegetables, cooked foods, and ready-to-eat foods
4. Cook raw food from animal sources (e.g., beef, pork, and poultry) thoroughly
5. Avoid consumption of raw (unpasteurized) milk or foods made from raw milk
6. Wash hands, knives, and cutting boards after handling uncooked foods
7. Use precooked or ready-to-eat foods as soon as possible; do not use them after the use-by date

Additional Recommendations for People at High Risk[a]

1. Avoid soft cheeses (e.g., queso, feta, Brie, Camembert) and blue-veined cheese; hard cheeses, cream cheese, cottage cheese, and yogurt need not be avoided

2. Heat leftover foods or ready-to-eat foods (e.g., hot dogs, deli meats) until steaming hot before eating

3. Consider avoiding foods from delicatessen counters[b]

4. Avoid refrigerated seafood products unless canned or shelf stable

---

[a] People immunocompromised by illness or medications, pregnant women, and the elderly.

[b] Although the risk of listeriosis associated with foods from delicatessen counters is relatively low, pregnant women and immunosuppressed people may choose to avoid these foods or to reheat cold cuts thoroughly before consumption.

Complication of successive pregnancies by a neonatal listerial infection is virtually unknown; therefore, intrapartum antibiotic therapy is not recommended for mothers with a history of perinatal listeriosis. No vaccine is available for listeriosis. Effective prevention of listerial infections can be achieved by administration of TMP-SMX, given as prophylaxis for *P. jirovecii* pneumonia, to recipients of organ transplants or to people with HIV.[168,169]

Acknowledgment

The author acknowledges the substantial contributions to this chapter from four previous editions of the textbook and also the skillful work that created Fig. 132.2.

Key Points

Listeria monocytogenes

Microbiology

- *L. monocytogenes* is a gram-positive rod; these organisms often are mistaken for diphtheroids, streptococci, or enterococci.

- Isolation of a "diphtheroid" from a normally sterile body fluid, particularly cerebrospinal fluid, should alert the clinician to the possibility of listeriosis.

Epidemiology

- Illness is primarily zoonotic, particularly in herd animals.
- Transmission occurs from mother to fetus/neonate in utero; in humans it occurs at birth.
- After the neonatal period the infection typically is a foodborne illness; highest risk foods are deli-style, ready-to-eat meats and unpasteurized cheeses.
- At-risk populations include neonates, older adults, pregnant women, and people with impaired cell-mediated immunity as a result of disease (e.g., malignancy, cirrhosis, diabetes, renal failure) or immunosuppressive therapy (e.g., corticosteroids, anti–tumor necrosis factor agents).

Clinical Features

- Bloodstream infection and meningoencephalitis are the most common invasive infections.
- Meningitis can be subacute.
- Neonatal infection occurs as both early and late onset disease, similar to *Streptococcus* group B infection.
- Acute febrile gastroenteritis occurs more often in outbreaks than sporadically; consider especially in a foodborne outbreak with negative results on routine stool cultures.

Diagnosis

- Consider especially in the following:

▪ Sepsis or meningitis in infants younger than 2 months of age

▪ Meningitis or parenchymal brain infection in people with impaired cell-mediated immunity

- Fever during pregnancy
- Subcortical brain abscess or brainstem infection

Treatment

- Ampicillin plus consideration of gentamicin is recommended for central nervous system infections.
- Cephalosporins are not adequate therapy.
- Trimethoprim-sulfamethoxazole is recommended for patients allergic to penicillin.

Other Gram-Positive Bacilli

Denise F. Bratcher

A number of pleomorphic, nonsporulating, gram-positive bacilli have long been identified as “diphtheroids” and dismissed as contaminants. However, many of these organisms can cause endocarditis and other serious diseases, especially in immunosuppressed patients. For this reason, coryneform bacteria isolated from clinical specimens should be identified as a matter of routine, particularly if they are found in pure culture, are from multiple specimens, or are found in immunocompromised patients.

Erysipelothrix rhusiopathiae

Erysipelothrix rhusiopathiae first was isolated in 1878 from mice by Koch. It later was identified as the cause of swine erysipelas and as a human pathogen. In recent years *E. rhusiopathiae* has become recognized as a cause of serious human diseases.[1]

Microbiology.

E. rhusiopathiae is a gram-positive, pleomorphic, non–spore-forming, nonmotile, encapsulated, aerobic or facultatively anaerobic bacillus. Older colonies can lose cell wall integrity, making them appear to be gram negative or gram variable. The organism grows readily on standard media and in conventional blood culture systems. Both rough and smooth colonies are noted on blood agar. Smears from rough colonies can show granular, nonbranching filaments. Some strains can cause α-hemolysis in 48 to 72 hours. *E. rhusiopathiae* is distinguished readily from other morphologically similar, gram-positive bacteria (*Listeria* species and diphtheroids) by an absence of motility, a negative catalase reaction, and hydrogen sulfide (H_2S) production. *E. rhusiopathiae* is oxidase and urease negative; it produces acid from glucose and lactose. A growth pattern in gelatin stab cultures that resembles a test-tube brush or a pipe cleaner is highly characteristic.

Epidemiology.

E. rhusiopathiae, a ubiquitous organism, is primarily a pathogen of animals. It has been isolated from wild mammals; various fowl, fish, and shellfish; and from domestic animals, such as pigs, sheep, cattle, and horses.[1,2] Contaminated soil is thought to be a source. Human infections often are to the result of occupational exposure to infected animals or contaminated animal products. People at risk include slaughterhouse workers, butchers, poultry workers, fishermen, fish marketers, veterinarians, farmers, and housewives.[2] The incidence of human infection is higher in the summer months. A 4 : 1 male preponderance may reflect male occupational exposure.

Clinical Manifestations.

The three major types of clinical disease are (1) the most common form, a localized, recurring but usually self-limited, cutaneous form, known as erysipeloid, which resembles streptococcal erysipelas; (2) a diffuse cutaneous form, which manifests with multiple skin lesions and systemic symptoms; and (3) a systemic form, which is marked by septicemia and endocarditis. Erysipeloid is a painful, inflammatory lesion of the skin that usually involves the hands and fingers and commonly occurs at the site of a scratch contaminated through contact with animals or other infectious material. The incubation period is 1 to 7 days (usually <4 days) after inoculation. The lesion appears with a characteristic purplish red hue and irregular, raised borders that spread peripherally as central clearing occurs. The lesion can spread proximally to involve an adjacent joint. Erysipeloid lesions usually recover in 1 to 4 weeks.

The diffuse cutaneous form of *E. rhusiopathiae* infection, with progression of violaceous lesions remote from the initial site, is rarely reported; it is associated more frequently with systemic symptoms, such as fever, malaise, arthralgia, myalgia, and severe headache. Although this form of the infection is not accompanied by bacteremia, its clinical course is more protracted and often complicated by recurrences.[2–4]

Septicemia and endocarditis are rare complications of *E. rhusiopathiae* infections, including occupationally acquired diseases.[1] Of more than 50 reported cases of bloodstream infection (BSI) caused by *E. rhusiopathiae,* approximately 90% were associated with endocarditis, which manifests as an acute or subacute process and is preceded by erysipeloid lesions in only one third of cases. The infection commonly affects people of normal health. It also affects native heart valves, involving the aortic valve in 70% of reported cases. Approximately 40% of patients have had previous heart disease. Valvular degeneration and abscess are common,[5] and intracranial complications have been reported.[6–9] Some experts have questioned whether *E. rhusiopathiae* bacteremia has a predilection for association with endocarditis.[10]

A variety of other infections associated with *E. rhusiopathiae* have been reported, such as BSI resulting from colonic perforation by a toothpick, and BSI in patients with lupus nephritis, HIV infection, and Crohn disease. Conditions associated with *E. rhusiopathiae* infection have included chronic meningitis, vertebral osteomyelitis, pyogenic arthritis, infected arthroplasty, pneumonia, peritonitis associated with peritoneal dialysis, intra-abdominal abscess, spinal abscess, necrotizing fasciitis, and infection from cat bite.[4,11–24]

Reported pediatric infections include endocarditis; BSI with acute leukemia, systemic lupus erythematosus, and HIV infection; systemic disease and pleural effusions; empyema, septic arthritis, pyomyositis, osteomyelitis, and localized infection of the knee.[3,6,25–30]

Diagnosis.

The diagnosis of erysipeloid relies on clinical recognition and an epidemiologic link to animal exposure. The organism is located deep in the reticular layer of the dermis; successful isolation from a skin lesion requires a full-thickness biopsy obtained from the peripheral quadrant of the lesion.[4] *E. rhusiopathiae* is isolated from blood in patients with septicemia or endocarditis. A high index of suspicion is necessary because these isolates occasionally are misidentified as streptococci or considered insignificant diphtheroids.[2,13] Serologic diagnostic methods are unreliable; however, polymerase chain reaction (PCR) methods may improve diagnostic accuracy in the future.[3]

Treatment.

Penicillin is considered the drug of choice for *E. rhusiopathiae* infections, based on exquisite susceptibility in vitro and limited clinical experience. Imipenem also has excellent activity against *E. rhusiopathiae* in vitro, followed by cefotaxime, clindamycin, tetracycline, and chloramphenicol. The organism is resistant to aminoglycosides, vancomycin, teicoplanin, and trimethoprim-sulfamethoxazole.[24] *E. rhusiopathiae's* resistance to vancomycin is noteworthy because this drug frequently is used as empiric therapy for endocarditis, especially in patients allergic to penicillin. Oral penicillin therapy usually is adequate for erysipeloid. *E. rhusiopathiae* BSI and endocarditis are best treated with aqueous penicillin G, 12 to 20 million units intravenously daily, in divided doses every 4 hours for 4 to 6 weeks.[1,2] No data are available to evaluate in vitro synergy with an aminoglycoside. Surgical intervention often is indicated for endocarditis.[31] Alternative drugs for patients allergic to penicillin include cephalosporins, imipenem, and fluoroquinolones.[10,32–34]

Rothia dentocariosa

Microbiology.

Rothia dentocariosa is a nonmotile, non–spore-forming, non–acid-fast, gram-positive bacillus with a variable morphology that includes coccoid and branching filamentous forms. Preferring aerobic conditions, *R. dentocariosa* grows less well in microaerophilic environments. The organism is slow growing and occasionally is isolated from anaerobic cultures that have been held longer than aerobic cultures. Colonies are either smooth and convex or rough with a "spoke-wheel" surface with scalloped edges.[35] *R. dentocariosa* produces acid from glucose, sucrose, maltose, and glycerol; it is catalase positive and oxidase, indole, and urease negative (although urease-positive and catalase-negative strains have been identified). *R. dentocariosa* hydrolyzes esculin, reduces nitrate, produces hydrogen sulfide, and typically is identified correctly by commercial identification systems. Microbial identification also has been confirmed by 16S (small subunit) ribosomal RNA (rRNA) gene sequencing.[36]

Epidemiology.

R. dentocariosa, part of the normal flora of the human mouth, first was isolated from dental caries in 1949 and remains a constituent of carious teeth.[37] This organism's pathogenic potential has been confirmed by a growing body of case reports, predominantly of infective endocarditis.

Clinical Manifestations.

The first human infection involving *R. dentocariosa,* a periappendiceal abscess, was reported in 1975. Since then, rare *R. dentocariosa* infections in people of normal health have been reported: BSI, periodontitis, pericoronitis, maxillary cyst, pilonidal cyst, and endocarditis.[38–48] Endocarditis associated with *R. dentocariosa* is reported most commonly. It typically involves native valves with preexisting cardiac abnormalities in patients with carious dentition or periodontitis, or who have undergone dental manipulation; occasionally prosthetic valves are involved.[41–51] Complications of endocarditis include brain abscess, multiple intracranial hemorrhages, mycotic aneurysms, and subarachnoid hemorrhages and aneurysm.[42–46,52] A few patients also had an underlying malignancy.[41,49] Additionally, *R. dentocariosa* has caused pneumonia and BSI in patients with underlying lung cancer and leukemia; peritonitis associated with peritoneal dialysis; septic arthritis in an immunosuppressed patient with rheumatoid arthritis; and arteriovenous fistula infection in a diabetic patient undergoing hemodialysis.[53–59] A proposed etiologic association with cat-scratch disease has not been verified.

Few *R. dentocariosa* infections have involved children.[47] Reported cases include BSI without endocarditis (in a neonate) and complicating lymphoproliferative disease after renal transplantation, congenital heart disease, and herpangina. Case reports also include severe exudative tonsillitis in a healthy 4-year-old child and corneal abscess in an 11-year-old boy who licked his fingertip before rubbing his eye.[60–64] Fetal blood cultures grew *R. dentocariosa* in an intrauterine fetal death.[65]

Treatment.

Penicillin appears to be the drug of choice for *R. dentocariosa* infections, based on clinical experience of cure in patients with endocarditis.[41–44,46,48–51] Most treatments also included an aminoglycoside. Although data are limited, the organism consistently is susceptible in vitro to penicillin, ampicillin, cephalothin, third-generation cephalosporins, erythromycin, rifampin, and vancomycin; it is variably susceptible to clindamycin, aminoglycosides, tetracycline, and trimethoprim-sulfamethoxazole. Determination of in vitro susceptibility is advisable because individual instances of β-lactam resistance and other variable resistance patterns have been described. Treatment failure has been observed in a few patients with endocarditis who initially were treated with vancomycin.

Rhodococcus (Corynebacterium) equi

Microbiology.

Rhodococcus equi (formerly *Corynebacterium equi*) is a gram-positive, encapsulated, intracellular bacillus that varies in shape from coccoid to long and club shaped. *R. equi* initially produces small, white, mucoid colonies, which become large, salmon-colored colonies on standard media in approximately 4 days. The bacilli can demonstrate a weak acid-fast reaction (often leading to their misidentification as mycobacteria) because of the presence of mycolic acids in their cell walls.[66] *R. equi* does not ferment carbohydrates or liquefy gelatin, and it is catalase positive and oxidase negative. *R. equi* strains have been categorized as virulent, intermediately virulent, and avirulent on the basis of virulence-associated antigens and plasmids.[67]

Epidemiology.

R. equi is a well-established pathogen in animals. The first human infection, a lung abscess, was described in 1967. Reports of *R. equi* infection are increasing, predominantly among immunocompromised patients, especially those with defects in cell-mediated immunity.[68] The natural habitat of *R. equi* is soil; infections are believed to be acquired by the respiratory route. *R. equi* is an intracellular organism that survives and replicates in macrophages by preventing fusion of phagolysosomes.[69] *R. equi* infections occur in patients with and without animal contact.

Clinical Manifestations.

Most reports of *R. equi* infection involve patients infected with HIV. (The associated mortality rate in patients with HIV is greater than 50%, compared with 20% in patients without HIV.)[70] The lung is the most commonly noted site in both immunocompetent and immunocompromised patients, and reports of infection in recipients of solid organ transplants are increasing.[71] The clinical course of pneumonia mimics mycobacterial disease (i.e., necrotizing, cavitary lesions and, commonly, upper lobe involvement). Endobronchial granulomas also have been reported.[66,72,73] Empyema, lung abscess, mediastinitis, malakoplakia, and other pulmonary manifestations have been described.[72,74–78]

Other reported clinical associations in immunocompetent and immunocompromised patients include BSI; diarrhea; meningitis; abscesses of the brain, thyroid, lung, adrenal glands, liver, spleen, and paravertebral area; skin and soft tissue infections; lymphadenitis; mastoiditis; peritonitis; granulomatous hepatitis; colonic polyps; pericarditis; osteomyelitis; mandibular osteitis; foot mycetoma and disseminated infection; endophthalmitis; keratitis after ocular surgery; orbital implant infection; and peritonitis complicating chronic ambulatory peritoneal dialysis.[79–108]

R. equi infections occasionally have been reported in children, often involving extrapulmonary sites. Such infections include pneumonia (complicated by brain abscesses, and cavitary lesions) in patients with AIDS, BSI (alone or associated with pneumonia, and lymphadenitis), malakoplakia, eye infections, meningitis resulting from orbital trauma, osteomyelitis following trauma, and wound infection resulting in pyogenic arthritis.[73,89,98,109–119] *R. equi* infections are reported less commonly among immunocompromised children than among immunocompromised adults. Infections have been reported in children with HIV, leukemia, chronic granulomatous disease, interferon γ–receptor deficiency, and ependymoma; other conditions that have been noted include toxic epidermal necrolysis and congenital hepatic fibrosis with polycystic kidney disease.[99,109–116,120–122] Neonatal infections include BSI, and meningitis following ventriculoperitoneal shunt insertion.[118,123,124]

Treatment.

The optimal treatment and duration of treatment for *R. equi* infections are unknown, and many different methods of susceptibility testing have been applied in case reports. *R. equi* generally shows in vitro susceptibility to erythromycin, rifampin, vancomycin, fluoroquinolones, aminoglycosides, and carbapenems. *R. equi* typically is resistant to penicillins, and susceptibility to clindamycin, tetracycline, chloramphenicol, and cephalosporins is variable.[86] *R. equi* resists intracellular killing by macrophages; treatment requires use of an antibiotic with intracellular activity. The choice of treatment is based on antimicrobial susceptibility testing, and combinations of antibiotics with bactericidal and intracellular activity are recommended strongly. Antibiotic-resistant mutants can easily be selected using monotherapy, and monotherapy has been ineffective in a number of cases.[78] Some experts suggest initial treatment with vancomycin plus a carbapenem, rifampin, macrolide, teicoplanin, fluoroquinolone, or an aminoglycoside, followed by oral therapy with a combination of erythromycin plus rifampin, or erythromycin plus ciprofloxacin, or rifampin plus ciprofloxacin. Others suggest an initial intravenous combination that includes imipenem as optimal. Azithromycin in combination with other antimicrobials appears to be an appropriate choice because it achieves high tissue levels.[125] Levofloxacin has been used with rifampin.[126,127] Because of the high incidence of relapse among immunocompromised patients, especially those with HIV infection, treatment is recommended for at least 2 months and possibly up to 6 months.[66,75,128] Surgical drainage or resection of lesions often is required.

Gardnerella vaginalis

Gardnerella vaginalis (formerly known as *Haemophilus vaginalis* and *Corynebacterium vaginale*) has been implicated as the cause of bacterial vaginosis (BV) since 1955. *G. vaginalis* is consistently isolated as the predominant organism in women with BV, but its role in the pathogenesis of this syndrome is confounded by isolation rates of up to 69% in vaginal specimens from healthy women.[129]

Microbiology and Pathogenesis.

G. vaginalis is a facultatively anaerobic, nonmotile, pleomorphic, gram-negative or gram-variable bacillus that is oxidase and catalase negative. Electron microscopic studies demonstrate a cell wall consistent with gram-positive and gram-negative organisms and a laminated cell wall typical of neither. *G. vaginalis* ferments a wide variety of carbohydrates, producing acetic acid as an end product. *G. vaginalis* does not reduce nitrate or hydrolyze urea. Colonies on blood agar are 0.3 to 0.5 mm in diameter after 48 hours of incubation; a distinct β-hemolysis is demonstrated on human and rabbit blood agar but not on sheep agar.

The ability of *G. vaginalis* to adhere to vaginal and urinary epithelial cells at a pH of 5 to 6 is thought to contribute to its role in the pathogenesis of BV and urinary tract infections.[130] Some experts hypothesize that other, undefined factors disturb the ecologic balance between *G. vaginalis* and *Lactobacillus* species in the female genital tract, allowing *G. vaginalis* and anaerobic organisms to proliferate, leading to BV.[131]

G. vaginalis also produces phospholipase, which breaks down phospholipids to arachidonic acid, producing a cascade of prostaglandins that may explain the relationship between BV and the onset of preterm labor.[132]

Epidemiology.

The incidence of bacterial vaginosis caused by *G. vaginalis* is difficult to define. Sexual transmission has been proposed as the main mode of transmission, which is supported by isolation of *G. vaginalis* of the same biotype from urethral cultures of men and their partners with BV.[133] Colonization of the genital tract also may result from transfer from an endogenous intestinal site.[134]

G. vaginalis is rare among prepubertal females.[135–139] In a study of prepubertal males with no history of suspected or known sexual abuse, *G. vaginalis* colonization of the urethra, glans, or rectum was not found.[140] The presence of *G. vaginalis* in a vaginal specimen from a prepubertal female or isolation from a symptomatic prepubertal boy should heighten suspicion of sexual abuse, but it is not incontrovertible evidence of it (see Chapter 54).[137,140]

Clinical Manifestations.

The clinical features of BV are addressed in Chapter 51. *G. vaginalis* also is a cause of postpartum or postabortion septicemia, and it is associated with fever, vaginal discharge, abdominal tenderness, and leukocytosis.[141] In rare cases BSI has been described in women undergoing gynecologic procedures and in men after urologic surgery or with urolithiasis.[142–144] *G. vaginalis* infection has been associated with endometritis, chorioamnionitis, episiotomy and hysterectomy wound infections, intrauterine infections, and vaginal abscess.[141–143,145] Urinary tract infections (UTIs) have occurred in both males and females, especially in pregnant women and renal transplant recipients.[146] Balanoposthitis, nonspecific urethritis, cystitis, and prostatitis in males have been associated with *G. vaginalis*.[145,147] Lung abscess, empyema, and BSI from inhalation pneumonia were reported in an individual with alcoholism.[148] In one report *G. vaginalis* also was associated with retinal vasculitis.[149]

Neonates with *G. vaginalis* septicemia, meningitis, cellulitis, conjunctivitis, and pneumonia have been reported.[150–154] *G. vaginalis* has been the presumed cause of osteomyelitis that complicated a cephalhematoma after use of an internal scalp electrode, and also of early onset infection of a scalp hematoma.[155,156] *G. vaginalis* was grown from the purulent exudate of a 20-month-old boy with balanitis without evidence of sexual abuse.[140] Other reports of pediatric *G. vaginalis* infection include UTIs.[157]

Diagnosis.

Culture of vaginal secretions is not recommended for diagnosis of BV.[158] Direct smear, especially Gram stain, is the preferred diagnostic test (to assess relative numbers of *G. vaginalis* and *Lactobacillus* species). Clue cells (epithelial cells coated peripherally with *G. vaginalis*) are observed on direct examination of vaginal secretions from patients with BV (see Fig. 52.1).[158] The addition of

10% potassium hydroxide to specimens results in a fishy, aminelike odor (known as the amine, or whiff, test). The clinical criteria for the diagnosis of BV are (1) a vaginal pH above 4.5; (2) positive results on the whiff test; (3) the presence of clue cells; and (4) a homogeneous, white, adherent vaginal discharge. The indirect fluorescent antibody method also detects *G. vaginalis* in specimens of vaginal secretions. Identification of the organism from culture is based on the demonstration of thin, gram-variable, catalase-negative rods that grow with a narrow zone of β-hemolysis after 48 hours of incubation.

Treatment.

Metronidazole (1 g/day orally in 2 divided doses for 7 days) is the drug of choice for treatment of BV, and initial cure rates are 90% or greater.[145] Other options include orally administered clindamycin (600 mg/day in 2 divided doses for 7 days), intravaginally applied metronidazole gel (0.75%, 5 g or one applicator once daily for 5 days) or clindamycin cream (2%, 5 g or one applicator at bedtime for 7 days). Treatment of sexual partners has not been shown to alter the clinical course of BV or to prevent relapsing or recurrent infections,[159,160] and the development of metronidazole resistance after treatment has been noted.[161] *G. vaginalis* isolates are susceptible in vitro to penicillin, ampicillin, erythromycin, clindamycin, chloramphenicol, trimethoprim, and vancomycin, providing options for treatment of extragenital infections.[162]

Lactobacillus Species

Epidemiology and Microbiology.

Lactobacillus species are normal flora of the human mouth, gastrointestinal tract, and female genital tract, where they produce lactic acid (resulting in a low vaginal pH) and competitively inhibit pathogenic organisms. *Lactobacillus* species are associated with dental caries.[163,164] Some species of *Lactobacillus* are used commonly as probiotics.

Lactobacilli are small, slender, nonmotile, gram-positive bacilli in chains. Immature colonies appear smooth, convex, and translucent. Organisms are microaerophilic or anaerobic and oxidase and catalase negative; they hydrolyze esculin and ferment carbohydrates. *Lactobacillus* can be difficult to identify correctly using most commercial identification systems. PCR assay, 16S rRNA gene sequencing, and matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry offer improved microbial identification.[165–167]

Clinical Manifestations.

Usually regarded as commensals or contaminants in clinical specimens, lactobacilli increasingly are identified as pathogens, although true *Lactobacillus* bacteremia accounts for only 0.1% of all positive blood cultures.[167] Endocarditis, the most common infection, frequently is associated with a structural heart defect or an immunocompromised state, including cardiac transplant.[168–170] Previous dental manipulation or parturition is a common factor in the affected patient's history. Endocarditis usually affects the left side of the heart and rarely involves prosthetic valves; involvement of the pulmonic and tricuspid valves has been reported.[171,172] Species associated with endocarditis include *L. acidophilus, L. casei* (subspecies *alactosus, casei,* and *rhamnosus*), *L. fermentum, L. jensenii, L. plantarian,* and *L. salivarius*. Failure of antibiotic treatment for endocarditis typically is associated with the use of single-drug regimens.

Cases of *Lactobacillus* endocarditis have occurred in children.[173] Species reported in children include *L. acidophilus* BSI in an infant[174]; *L. casei* BSI in a child with a congenital HIV infection[175]; *L. iners* pericarditis in an infant[176]; *L. rhamnosus* BSI and pericarditis and BSI and subsequent meningitis in recipients of bone marrow transplants[177,178]; and fatal pneumonia caused by *L. rhamnosus* in a child with aplastic anemia.[179] In one series, four cases of *Lactobacillus* BSI in children were reported: *L. rhamnosus* in an infant with necrotic bowel, *L. sakei* ssp. *carnosus* in a neutropenic patient with an ependymoma, *L. curvatus* after trauma, and *L. paracasei* ssp. *paracasei* after a burn.[180] A retrospective review of clinical isolates identified 41 *Lactobacillus* species isolated from 40 children, including *L. acidophilus, L. fermentum, L. jensenii, L. catenaforme,* and others.[181] Sources for these isolates included abscesses (dental, subcutaneous, vulvovaginal, abdominal, subdiaphragmatic, lung, and tonsillar), pneumonia, ear infection, catheter-related BSI, and conjunctivitis. Infections were polymicrobial in 90% of patients.

Clinical infections caused by *Lactobacillus* species typically occur among immunocompromised patients; they include BSI, pneumonia, empyema, abscesses (liver, spleen, pelvic, peritonsillar and retropharyngeal, and abdominal wall), meningitis, peritonitis, endometritis, endophthalmitis, UTI, cholecystitis, empyema of the gallbladder, and septic arthritis.[178,182–204] Little is known about the pathogenesis of infection. The most common *Lactobacillus* species reported as pathogenic are *L. casei, L. fermentum,* and *L. acidophilus*, although species often are not identified completely.

In rare cases, probiotic-associated invasive disease attributable to *L. rhamnosus* GG has been reported in children. Short bowel syndrome appears to be the most common clinical association in children presenting with *L. rhamnosus* GG BSI after enteral *L. rhamnosus* GG therapy.[205] Other pediatric cases associated with *L. rhamnosus* GG include a patient with congenital heart disease who had BSI and an atrial wall thrombus; an infant with trisomy 21 and probiotic-associated aspiration pneumonia after respiratory viral infection; a teen with ulcerative colitis and BSI; and a newborn with intrauterine growth retardation.[206–211] Three reports found no significant change in the rate of *L. rhamnosus* BSI after introduction of probiotics clinically in Finland and Sweden.[208,212,213] A review of the safety of probiotics suggests they are safe for clinical use despite these rare infections.[214,215] The U.S. Food and Drug Administration has defined groups potentially at risk for adverse events in probiotic clinical trials; these include immunocompromised people, premature infants, and people with short bowel syndrome, central venous catheters, or cardiac valve disease.[215]

Treatment.

Antimicrobial susceptibility seems to be species dependent. Susceptibility data are scarce, and neither standards for susceptibility testing nor guidelines for interpretation have been established. Salminen et al.[216] found low minimum inhibitory concentrations (MICs) among blood isolates for imipenem, piperacillin-tazobactam, erythromycin, and clindamycin. Vancomycin MICs were high for all species except *L. gasseri* and *L. jensenii.* Susceptibility to penicillin and cephalosporins was variable.

High-dose penicillin or ampicillin plus gentamicin are synergistic, and combination therapy typically has been considered the standard of care in endocarditis and other serious or deep-seated infections. Optimal antibiotic therapy is best guided by the clinical presentation, susceptibility testing of the isolate, and consideration of companion isolates.

Tsukamurella Species

Epidemiology and Microbiology.

Tsukamurella species first were isolated from the ovaries of bed bugs in 1941; they are also found in soil and sludge. The first human isolate, then known as *Gordona aurantiaca,* was described in 1971 from sputum samples of patients with chronic pulmonary disorders.[217] On the basis of gene sequences analysis, *Tsukamurella* was proposed as a genus in 1988. Seven species have been identified, and six have been reported to cause infections in humans: *T. inchonensis, T. paurometabola, T. pulmonis, T. spurrae*, *T. strandjordae,* and *T. tyrosinoslovens.*[218,219]

Tsukamurella are gram-positive, aerobic, nonmotile, non–spore-forming bacilli. They are partially acid fast because of the mycolic acid in the cell envelope. They grow rapidly on MacConkey agar and appear as yellow, rough, irregular, flat, dry colonies, often with a suedelike appearance.[217] *Tsukamurella* can be misidentified because it has characteristics similar to those of *Rhodococcus, Nocardia, Corynebacterium,* and rapidly growing mycobacteria.[217] Advanced molecular methods (e.g., PCR and 16s rRNA gene sequencing) can distinguish *Tsukamurella* from other genera but may not discriminate among *Tsukamurella* species.[219,220]

Clinical Manifestations.

Tsukamurella infections in humans are rare and usually are related to medical devices. The most commonly seen type is catheter-related BSI; other types include dialysis catheter–related peritonitis, infections related to an implantable cardioverter-defibrillator and to a knee prosthesis, keratitis after trauma, corneal grafting, or ocular abnormalities.[217–230] *Tsukamurella* pulmonary infections have occurred in patients with underlying pulmonary disease, in an AIDS patient (with a cavitary lesion), and as a cause of community-acquired pneumonia.[231–235] Septic pulmonary emboli were noted to complicate a catheter-related BSI caused by *T. tyrosinosolvens*.[236] Local skin infection, subcutaneous abscess with necrotizing fasciitis, conjunctivitis, cerebellar abscess complicating chronic otitis media, and fatal meningitis in a patient with leukemia have been associated with *Tsukamurella* species.[217,218,237–239]

Among children three cases of *Tsukamurella* BSI have been reported in immunosuppressed patients with central venous catheters: *T. strandjordae* infection in a patient with acute myelogenous leukemia[240]; *T. pulmonis* infection in a patient who had received a bone marrow transplant for severe combined immunodeficiency; and infection by an untyped *Tsukamurella* species in an infant with myelodysplastic syndrome.[217]

Two *Tsukamurella* pseudo-outbreaks caused by laboratory contamination of clinical specimens and an outbreak of BSI among oncology patients as a result of improper preparation of a saline flush have been reported.[241–243]

Treatment.

Limited data are available on antimicrobial susceptibility testing of *Tsukamurella* isolates; reported susceptibility patterns are similar across *Tsukamurella* species. *Tsukamurella* typically is resistant to penicillins and cephalosporins but susceptible to amikacin, ciprofloxacin, clarithromycin, imipenem, and sulfamethoxazole.[217] *T. paurometabola* demonstrates high-level resistance to imipenem.[244] Combination therapy typically has been used to treat *Tsukamurella* infections.[217,233] Catheter removal is indicated in catheter-related infections.

Cellulosimicrobium (Formerly *Oerskovia*) Species

Epidemiology and Microbiology.

Human infections caused by *Nocardia*-like, diphtheroid-like organisms of the *Cellulosimicrobium* (formerly *Oerskovia*) genus have been described rarely. The genus consists of three species, *C. cellulans* and *C. funkei* (formerly *O. xanthineolytica* and *O. turbata*, respectively), and *C. terreum,* which are found in grass cuttings, aluminum hydroxide gel, and soil in many parts of the world. *Cellulosimicrobium* organisms are gram-positive, branched, filamentous, non–acid-fast bacilli that fragment into motile rods. The bright yellow pigment of colonies is characteristic. Organisms produce acid from glucose, lactose, maltose, sucrose, and xylose. They hydrolyze esculin and reduce nitrate, and they are catalase positive and oxidase and urease negative. *Cellulosimicrobium* organisms can be identified by 16s rRNA sequencing and MALDI-TOF mass spectrometry.[245,246]

Clinical Manifestations.

Cellulosimicrobium infections are rare in humans and usually occur in immunocompromised patients with indwelling foreign devices. Case reports of *C. cellulans* BSI have involved patients with alcoholic cirrhosis, short bowel syndrome, colon cancer, and breast cancer.[247–250] Endocarditis has been reported in recipients of bone marrow and renal transplants.[251,252] *C. cellulans* has caused dialysis-related peritonitis[253–256] (including in a 13-year-old with recurrent and culture-negative peritonitis),[255] meningitis associated with a ventriculoperitoneal shunt,[257] a prosthetic knee joint infection,[258] septic arthritis after a penetrating thorn injury, endophthalmitis after penetration by a foreign body and after ophthalmologic surgery,[259,260] flexor sheath tenosynovitis in a patient with multiple splinters,[261] keratitis in a contact lens wearer,[262] and chronic tongue ulcerations in a patient with HIV infection.[263] A case of early onset neonatal sepsis also has been reported.[264]

C. funkei has caused two cases of BSI (in a patient with AIDS[265] and in a 3-year-old with leukemia[266]); endocarditis in a patient with Crohn disease associated with ankylosing spondylitis and aortic insufficiency[267] and in another patient after aortic valve replacement complicated by cerebral abscesses[268]; dialysis-related peritonitis[245]; and an axillary abscess in a patient with AIDS.[269] Individual cases of pyonephrosis[270] and BSI related to a contaminated parenteral nutrition solution[271] were caused by unspecified *Cellulosimicrobium* species.

Treatment.

Antimicrobial susceptibility varies among the isolates reported.

However, using the interpretive guidelines for corynebacteria, *Cellulosimicrobium* species consistently are susceptible to vancomycin (considered the therapy of choice) and imipenem. They are variably susceptible to amikacin, ampicillin, cephalosporins, ciprofloxacin, levofloxacin, penicillin, tetracyclines, and trimethoprim-sulfamethoxazole, and they are resistant to clindamycin, erythromycin, gentamicin, and tobramycin. Susceptibility to linezolid has been reported, and therapy with rifampin combined with other agents has been described.[246] Optimal therapy generally involves removal of hardware or foreign bodies.[246,256]

Kurthia Species

Microbiology.

Kurthia species are coryneform organisms identified as short, plump, non–spore-forming, aerobic, gram-positive bacilli. These organisms grow poorly in anaerobic environments; demonstrate motility at 36°C but not at 21°C; are catalase positive, oxidase negative, and urease positive after 24 hours incubation; and do not ferment carbohydrates or reduce nitrate.

Clinical Manifestations.

Kurthia species have been isolated from clinical specimens, including feces, sputum, and those obtained from a pilonidal cyst and from the conjunctiva, although these isolates were not considered significant clinically. *K. zopfii* was isolated from the blood of an infant with septicemia.[272] A sexually transmitted zoonotic infection (urethritis) caused by *K. gibsonii* was reported in an adult male.[273] The course of a 31-year-old narcotic user who had endocarditis of native aortic valves caused by *K. bessonii* was complicated by a cusp abscess and fistula.[274]

Treatment.

Kurthia species typically are susceptible to penicillin, ampicillin, carbenicillin, cephalothin, gentamicin, amikacin, erythromycin, chloramphenicol, and trimethoprim-sulfamethoxazole. They are resistant to oxacillin, clindamycin, and kanamycin.

Key Points

Gram-Positive Bacilli (Other Than *Listeria monocytogenes*)

- A number of gram-positive bacilli previously identified as diphtheroids increasingly have been implicated as human pathogens, especially among immunocompromised patients.

- *Erysipelothrix rhusiopathiae* causes three forms of clinical disease: localized cutaneous, diffuse cutaneous, and systemic. Septicemia and endocarditis occur in rare cases.

- *Rothia dentocariosa* is associated with endocarditis.

- *Rhodococcus equi,* typically seen in patients infected with HIV, can cause pulmonary infections that mimic mycobacterial disease.

- *Gardnerella vaginalis* commonly is associated with bacterial vaginosis and can cause urologic and gynecologic infections.

- *Lactobacillus* endocarditis is associated with probiotic-associated invasive disease attributable to *L. rhamnosus* GG has bee reported in rare cases.

- *Tsukamurella, Cellulosimicrobium,* and *Kurthia* species can cause infection in humans in rare cases.

Mycobacterium tuberculosis

Silvia S. Chiang, Jeffrey R. Starke

The genus *Mycobacterium* consists of a diverse group of acid-fast bacilli (AFB) with a lipid-rich cell wall. The bacilli are aerobic, non–spore-forming, nonmotile, and slightly curved or straight organisms. Mycobacteria take up stain poorly but retain specific dyes despite treatment with acid-alcohol solutions. This acid-fast property is demonstrated with fuchsin stain techniques, such as the Ziehl-Neelsen and Kinyoun methods, or the fluorochrome method using auramine and rhodamine stains.

Tuberculosis (TB) disease results from infection with any member of the *Mycobacterium tuberculosis* complex: *M. tuberculosis* (which accounts for most human TB), *M. bovis, M. africanum* (which causes one half of pulmonary TB in West Africa), and *M. canetti* (which may be an ancestral strain of *M. tuberculosis*). The complex also includes several species that cause TB primarily in animals, and occasionally through animal exposure, in humans: *M. microti* (i.e., rodents), *M. pinnipedii* (i.e., aquatic mammals), and *M. capral* (i.e., animals in Europe).

M. bovis, the primary cause of TB in cattle, causes a small but significant portion of human TB cases, which are acquired primarily through unpasteurized dairy products, although person-to-person transmission has been documented. The incidence of *M. bovis* likely is underestimated because most diagnostic tests cannot differentiate between *M. bovis* and *M. tuberculosis*. Disease caused by *M. bovis* is similar to that caused by *M. tuberculosis*, but *M. bovis* enteritis and other forms of extrapulmonary disease are more common among children and immunocompromised adults. *M. bovis* usually is identified by its intrinsic pyrazinamide resistance. Isolated pyrazinamide resistance occurs rarely in *M. tuberculosis* infection.

Immunology and Pathogenesis

Exposure to *M. tuberculosis* can result in elimination of the bacteria, TB infection (an asymptomatic state evidenced only by a positive test of infection), or clinically significant TB disease (Box 134.1). TB diseases mirror a continuum of immunologic responses. At one end of the spectrum, severe disseminated disease represents a failure of T-lymphocyte proliferation in response to *M. tuberculosis* and often is associated with a negative tuberculin skin test (TST) result.[1–5] In contrast, patients with TB pleuritis have an effective immune response. Few bacilli are found in the pleural fluid and tissue, and resolution without therapy is common.[4]

Box 134.1

Terminology Related to *Mycobacterium tuberculosis* Exposure, Infection, and Disease

Exposure occurs when the child has had significant contact ("shared the air") with an adult or adolescent with infectious tuberculosis. Not all children after exposure progress to infection.

Infection indicates that *M. tuberculosis* has invaded the lung, draining lymphatics, as evidenced by a reactive TST or positive IGRA result, but has not resulted in any signs, symptoms, or chest radiograph abnormalities (except for calcifications in the lung parenchyma and/or regional lymph nodes). Not all children with tuberculosis infection progress to disease.

Disease occurs when intrathoracic or extrathoracic signs or symptoms or radiographic manifestations (other than calcifications in the lung parenchyma and/or regional lymph nodes) caused by *M. tuberculosis* are apparent.

IGRA, interferon γ release assay; TST; tuberculin skin test;

M. tuberculosis typically enters the body through the respiratory tract, where mucociliary transport and cough serve as the first line of defense. After *M. tuberculosis* reaches the alveolus, the Ghon focus develops. Bacilli drain from this granulomatous focus along local lymphatics to regional lymph nodes. Together, the Ghon focus, lymphangitis, and regional lymphadenopathy form the Ghon complex. Most immunocompetent persons contain the infection within the Ghon complex and never develop TB disease. However, failure to achieve initial control of the infection leads to early disease. In reactivation disease, tubercle bacilli are disseminated by bacteremia to lung fields and distant body sites. The host may successfully contain the infection but develop reactivation disease years later if there is disruption of the host-pathogen balance.

Immunologic defenses against *M. tuberculosis* primarily are mediated by $CD4^+$ T lymphocytes and macrophages. *M. tuberculosis*–specific $CD4^+$ lymphocytes primarily produce type 1 helper T-lymphocyte (Th1) cytokines, which include interferon γ (IFNγ) and tumor necrosis factor-α (TNF-α). The protective roles of these cytokines against *M. tuberculosis* are demonstrated by the increased TB risk among patients treated with anti-TNF monoclonal antibodies and those with inherited defects in IFNγ pathways.[6–9] Although $CD8^+$ lymphocytes, neutrophils, and natural killer cells manifest mycobacteriostatic effects in vitro, their clinical significance remains unclear. The role of B lymphocytes also is undefined, although they are found in substantial numbers in granulomas. Several in-depth reviews describe the immune response to *M. tuberculosis*.[1–5]

Epidemiology

Transmission

Transmission of *M. tuberculosis* usually occurs person to person through mucous droplets that become airborne when an individual with pulmonary TB coughs or sneezes.[10] Droplets containing tubercle bacilli dry and become droplet nuclei, which can remain suspended in air for hours. Only droplet nuclei less than 10 μm in diameter can reach the alveoli. In rare cases, transmission occurs by direct contact with infected body fluids (e.g., urine, wound drainage), fomites (e.g., syringes, gastric lavage tubes), or improperly cleaned bronchoscopes.

The most important marker of contagiousness is the visualization of AFB in a sputum smear.[11–14] Young children with pulmonary TB have paucibacillary endobronchial secretions and diminished force of cough, and they therefore rarely infect others.[15,16] Because adolescents with reactivation pulmonary TB have a greater bacillary burden and stronger cough, they can be contagious and should be treated with the same infection control measures used for adults.[17–19] Most TB outbreaks in pediatric healthcare facilities have been linked to adult or adolescent visitors.[20,21] Adult and adolescent hospital visitors to children with suspected TB should be screened for cough, and coughing visitors should undergo chest radiography to exclude them as sources of transmissible infection.[15,16,20,21]

A patient is deemed no longer contagious on the basis of symptom improvement, decreased number of AFB in the sputum smear, radiographic improvement, and adherence to an effective treatment regimen.[17] Epidemiologic and animal transmission studies indicate that most patients with drug-susceptible TB become noncontagious within 2 weeks of starting effective treatment. Many patients become noncontagious within several days, although some patients, especially those with multidrug-resistant organisms remain infectious for weeks to months.

Routes of Infection

An estimated one third of the world's population is infected with *M. tuberculosis*, including 66 million children younger than 15 years of age.[22] In recent surveys from five Asian and African countries, the prevalence of childhood TB infection ranged from 7% (Nepal) to 23% (Somalia).[23–27] In crowded parts of Cape Town, South Africa, which has one of the world's highest TB rates, TB infection was documented among 28% of 5- to 10-year-old children and 42% of 11- to 15-year-old children.[28]

The overall prevalence of TB infection among US children is 1.1%; prevalence among foreign-born children is 12%, compared with 0.3% for US-born children.[29] From 2007 to 2012, 13% of US immigrant and refugee children tested positive for TB infection.[30]

Most children acquire TB infection from close contact with a contagious adult or adolescent living in the same household. Consequently, the most efficient method of finding children infected with *M. tuberculosis* is household contact investigation of adults with contagious pulmonary TB.[31] On average, 30% to 50% of household contacts of a case have a reactive TST result. The infectiousness of the source case and the degree and duration of contact mediate the likelihood of transmission. For instance, a child has a higher risk of infection if the source case is the primary caregiver or sleeps in the same room.[32,33] Although children are less frequently infected from casual, nonhousehold contacts, outbreaks have occurred in schools, childcare facilities, churches, and on school buses. In most cases, a highly contagious adult working in the area was the source case. During a 1994 elementary school outbreak traced to a teacher with longstanding, unrecognized pulmonary TB, almost 50% of the students had *M. tuberculosis* infection, and 11% had radiographic evidence of disease.[34]

Disease Incidence and Epidemiology

The World Health Organization (WHO) estimates about 10 million incident TB cases and 3 million TB-related deaths in the world every year. According to the WHO, approximately 550,000 of these cases occurred among children younger than 15 years of age.[35–37] However, modeling studies have concluded that the true pediatric disease incidence is 800,000 to 1,000,000 cases per year.[22,38]

Epidemiology of childhood TB requires thorough knowledge of disease epidemiology for adults. From 1953 to 1984, the US TB (i.e., TB disease in this chapter unless stated otherwise) incidence declined by an average of 6% per year. However, from 1985 to 1993, the number of TB cases reported in the United States increased by 18%.[39] The most important factors underlying the resurgence of TB were the human immunodeficiency virus (HIV) epidemic, influx of immigrants from high-prevalence countries, and inadequate implementation of public health policy. Fortunately, increased TB control efforts in the United States starting in the 1990s led to a steady decrease in TB incidence resulting in an all-time low of 9,582 cases in 2013 (Fig. 134.1).[39]

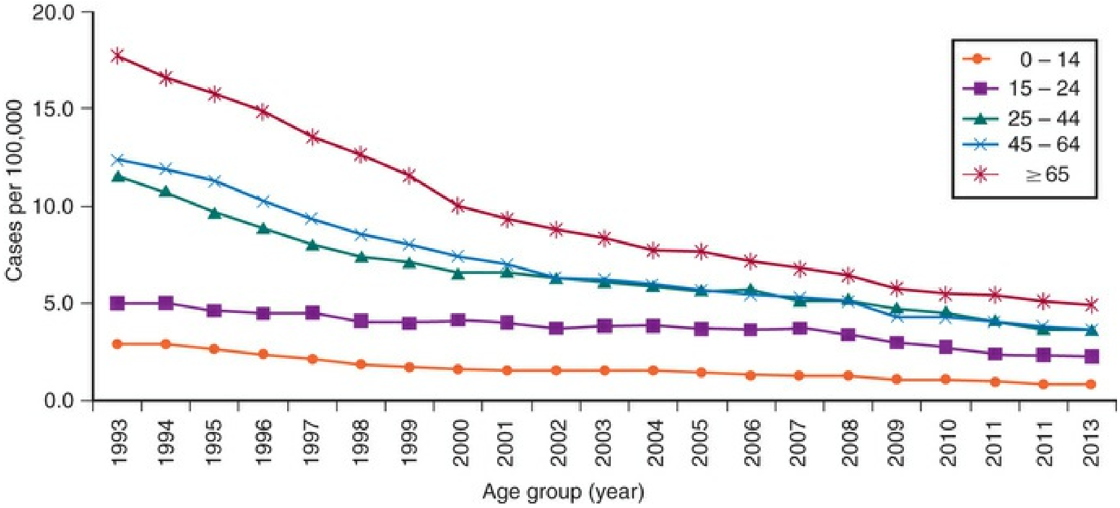

FIGURE 134.1 Reported tuberculosis cases per 100,000 people by age group in the United States, 1993 to 2013. (Data from the Centers for Disease Control and Prevention. Reported Tuberculosis in the United States, 2013. Atlanta, GA, CDC, 2014.)

When TB was more prevalent in the United States, risk of exposure to a contagious adult was uniformly high throughout the population. With the currently low TB incidence, exposure to *M. tuberculosis* is more confined to well-defined populations. The proportion of patients with TB disease who are foreign born has risen steadily since 1993 and reached an all-time high of 65% in 2013. Five countries of origin (i.e., Mexico, Philippines, Vietnam, India, and China) accounted for 54% of the cases.[39] Increased risk of TB infection historically has been associated with intravenous drug use and residence in jails, prisons, and homeless shelters, especially in large urban sites. Metropolitan areas with at least 500,000 people accounted for 67% of the US population and 80% of TB cases in 2013.[39]

The incidence of childhood TB in the United States declined by approximately 6% per year between 1953 and 1980. From 1980 through 1987, rates stabilized and then began a steady rise in 1988. In 1993, 1721 TB cases were reported in children younger than 15 years of age, a 40% increase over 1987. By 2013, the number of TB cases in children younger than 15 years had declined to 483, a 72% reduction since 1993.[39] Of these 483 cases, 61% occurred in children younger than 5 years of age, reflecting this age group's high risk of disease progression, and 20% occurred among foreign-born children.[39] Hispanics and Asians had the highest percentage of cases among US-born children and foreign-born children, respectively.[39] Fifty-seven percent of reported cases among children younger than 15 years occurred in seven states (i.e., California, Florida, Georgia, Illinois, Nevada, New York, and Texas), with 34% in California and Texas alone.[39]

The risk of progression from *M. tuberculosis* infection to disease is age dependent and is highest among children younger than 2 years of age, likely due to a suboptimal immunologic response.[1] Disease risk is low between 5 and 10 years of age, rising again during early adolescence (Table 134.1).[40] Age also affects disease phenotype. Infants and young children are more likely to have pulmonary, meningeal, disseminated, and lymphatic TB, whereas older children and adolescents more commonly have reactivation pulmonary, pleural, genitourinary, or peritoneal disease.[41–44] Among younger children, the sex ratio for TB disease is approximately 1 : 1, but girls have a higher incidence during early adolescence.[42,45–49]

TABLE 134.1

Age-Specific Risk of Progression to Tuberculosis in Immunocompetent Children

Age at Primary Infection (yr)	Percentage (%) of Children Who Do Not Develop Disease	Percentage (%) of Children Who Develop Pulmonary Disease	Percentage (%) of Children Who Develop Meningitis or Disseminated Disease
<1	50	30–40	10–20
1–2	85–90	10	2–5
2–5	95	5	0.5
5–10	98	2	<0.5
>10	80–90	10–20	<0.5

Data from Marais BJ, Gie RP, Schaaf HS, et al. The natural history of childhood intra-thoracic tuberculosis: a critical review of literature from the pre-chemotherapy era. Int J Tuberc Lung Dis 2004;8:392–402.

Drug-Resistant Tuberculosis

Drug-resistant TB poses a significant threat to global TB control. The spread of drug resistance stems from many factors: poor public health infrastructure (e.g., delays in the diagnosis of drug resistance, inconsistencies in TB medication supply), inadequate treatment (e.g., unmonitored therapy, nonadherence, incorrect use of anti-TB agents), inefficient infection control, and the HIV epidemic.[50,51] India, China, and the former Soviet republics account for more than one half of the world's cases of multidrug-resistant TB (MDR-TB) defined as resistance at least to isoniazid and rifampin (Fig. 134.2).[37]

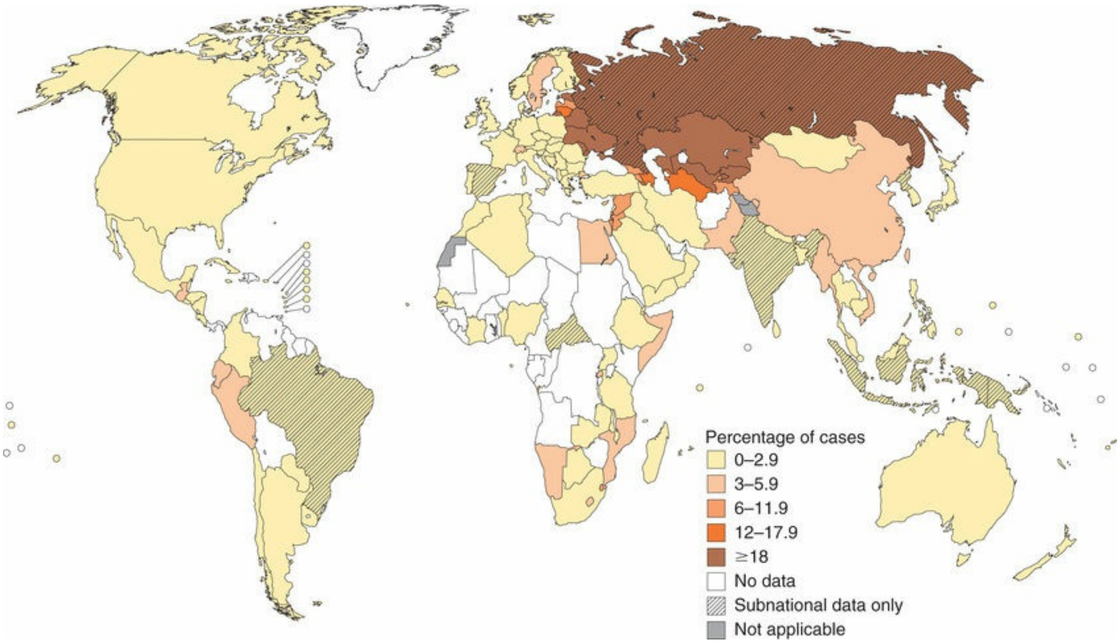

FIGURE 134.2 Percentage of multidrug-resistant tuberculosis cases estimated to occur among notified pulmonary tuberculosis cases. (Data from the World Health Organization. Global Tuberculosis Report, 2015. Geneva, Switzerland, WHO, 2015.)

In 2013, the WHO estimated that 8% of new TB cases and 14% of previously treated cases had isoniazid resistance without concurrent rifampicin resistance, and an additional 4% of new cases and 21% of previously treated cases had MDR-TB. Of greater concern, 30% of MDR-TB cases met criteria for pre-extensively drug-resistant TB (i.e., resistant to at least isoniazid, rifampin, and a fluoroquinolone or a second-line injectable agent) or extensively drug-resistant TB (XDR-TB) (i.e., resistant to at least isoniazid, rifampin, a fluoroquinolone, and a second-line injectable agent).[37] Surveillance gaps, caused in large part by insufficient resources for drug susceptibility testing, limit the quality of drug-resistant TB epidemiology. Underdetection of resistant TB is greater for children, who frequently have culture-negative disease.

Although the WHO has not published estimates of childhood drug-resistant TB, modeling work estimated an annual incidence of 88,000 cases of isoniazid-resistant TB without concurrent rifampin resistance and 32,000 MDR-TB cases among children younger than 15 years of age. Southeast Asia and the Western Pacific regions bear the brunt of these cases.[38,52]

In the United States, isolated strains demonstrating multidrug resistance and isolated isoniazid resistance have hovered around 1% and 9%, respectively, for the past several years. Among children younger than 15 years of age with culture-confirmed disease, approximately 2% have MDR-TB.[39,52,53] Patients with any of the following characteristics have a higher risk of drug-resistant TB: previous treatment for TB disease, birth in a country with a high drug-resistant TB prevalence (see Fig. 134.2), or contact with a source case previously treated for TB disease or born in a country with a high drug-resistant TB burden.

Tuberculosis in Immunocompromised Children

The HIV epidemic has affected profoundly the epidemiology of childhood TB.[54–56] HIV-infected adults are more likely to have TB infection, pulmonary disease, and lack of classic features allowing prompt diagnosis. Children with HIV infection have a higher risk of progressing from TB infection to disease.

For adults and children, pulmonary TB is a defining condition for acquired immunodeficiency syndrome (AIDS). Studies have suggested that HIV-seronegative and HIV-seropositive adults with smear-positive pulmonary TB are equally infectious. However, HIV-infected adults with pulmonary TB may be less likely to have a positive acid-fast sputum smear than HIV-seronegative adults. A retrospective study in Florida observed a rise in childhood TB after an increase in pulmonary TB among HIV-infected adults in the community.[57]

Clinical and autopsy studies in countries with a high TB burden demonstrate excessive risk of TB disease among HIV-infected cohorts of children.[58–61] In economically developing nations, the underdiagnosis of childhood TB likely is greater among HIV-infected children because of similarities in clinical presentation to other opportunistic infections, frequent skin test anergy, and elusive culture confirmation. All children with suspected TB disease should be tested for HIV infection.

Other causes of immune suppression—including malignancies and their therapy and use of high-dose corticosteroids—have been associated with higher rates of TB disease. Anti-TNF drugs used to control inflammatory bowel and rheumatologic diseases greatly increase the risk of rapid progression from TB infection to disease in adults.[62,63]

Clinical Manifestations

Intrathoracic Disease

Pulmonary Disease

Most children infected with *M. tuberculosis* do not develop signs, symptoms, or radiographic abnormality.[40] However, the occasional child may experience several days of low-grade fever and mild cough at the start of infection. Other children may have fever and mild systemic symptoms at 3 to 12 weeks after acquisition of infection; these symptoms resolve over 1 to 3 weeks.

The Ghon complex affects lobes of the lung equally, and 25% of cases have multiple parenchymal foci.[64] Initial inflammatory response is not usually visible radiographically, but a localized, nonspecific infiltrate can appear. Within days, infection spreads to regional lymph nodes. As tissue sensitivity develops, inflammation in lung and lymph nodes intensifies. The hallmark of childhood pulmonary TB is disproportionately enlarged regional lymph nodes compared with a relatively minor parenchymal focus (Fig. 134.3). Because approximately 70% of Ghon foci are subpleural, the initial presentation commonly includes localized pleural reaction.

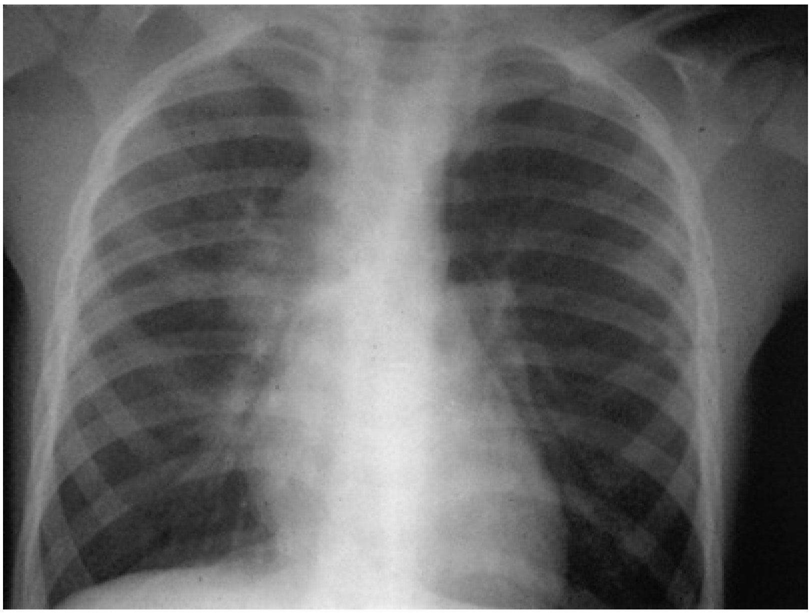

FIGURE 134.3 Right-sided hilar lymphadenopathy with minor parenchymal infiltrate in a 3-year-old boy with pulmonary tuberculosis. (Courtesy S. S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

In most children, lung inflammation and adenopathy resolve spontaneously and quickly, often by the time the chest radiograph is obtained. These children have successfully contained the tubercle bacilli but can develop reactivation disease in the future. Other children, particularly infants, progress to disease. Lymph nodes continue to enlarge and can compress airways, causing partial or complete bronchial obstruction.[64] The inflammatory response can erode the bronchial wall, leading to luminal infection. This process also can lead to partial or complete bronchial obstruction. A common radiographic sequence is adenopathy followed by localized hyperinflation and then atelectasis of contiguous parenchyma, referred to as segmental lesions (Fig. 134.4). This radiographic picture is different from other bacterial pneumonias and mimics foreign body aspiration and other obstructive disorders.

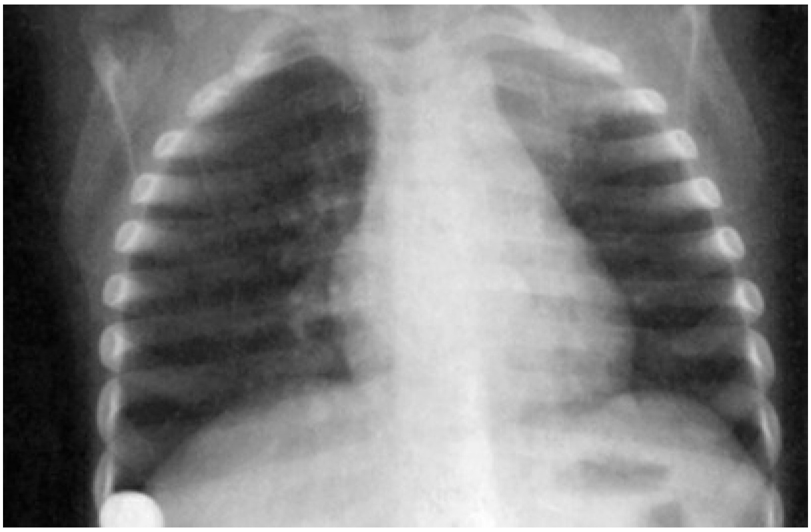

FIGURE 134.4 Mediastinal adenopathy and left upper-lobe segmental lesion in a child with pulmonary tuberculosis.

Although rare, obstructive emphysema of a lobar segment occurs most often in children younger than 2 years. Obstruction usually resolves spontaneously, but corticosteroids may hasten the process; complete resolution often takes several months. Up to 40% of children younger than 1 year of age with *M. tuberculosis* infection develop a segmental lesion, compared with 15% of children 11 to 15 years of age. Occasionally, the radiographic abnormality is lobar pneumonia, which is indistinguishable from acute bacterial pneumonia (Fig. 134.5). Enlarged subcarinal nodes can impinge on the esophagus, causing swallowing difficulty or the development of a bronchoesophageal fistula. Other enlarged nodes can compress the subclavian vein, causing upper extremity edema. Nodes can rupture into the mediastinum and lead to supraclavicular adenitis (Fig. 134.6).

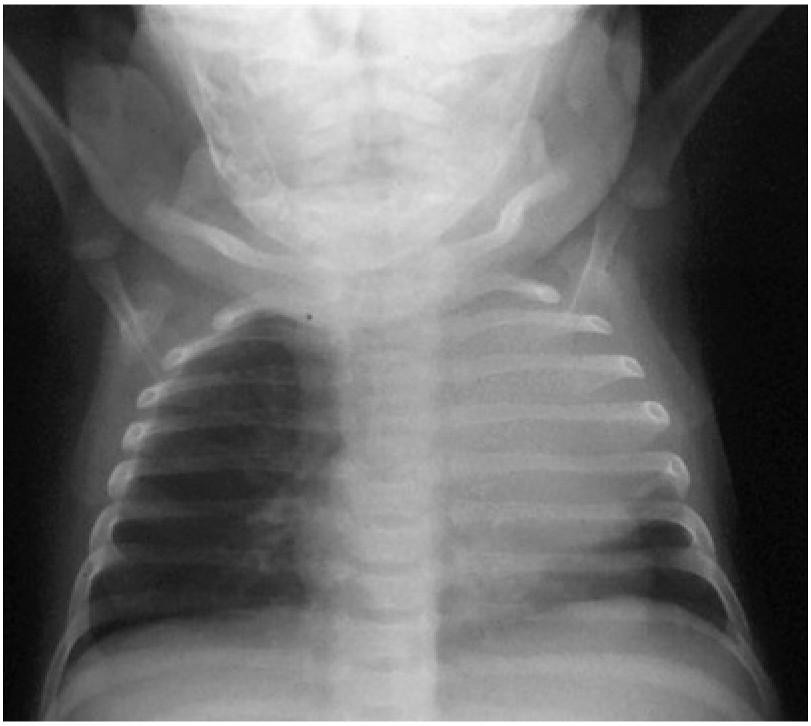

FIGURE 134.5 Left upper-lobe consolidation in a 16-month-old child with pulmonary tuberculosis. (Courtesy S. S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

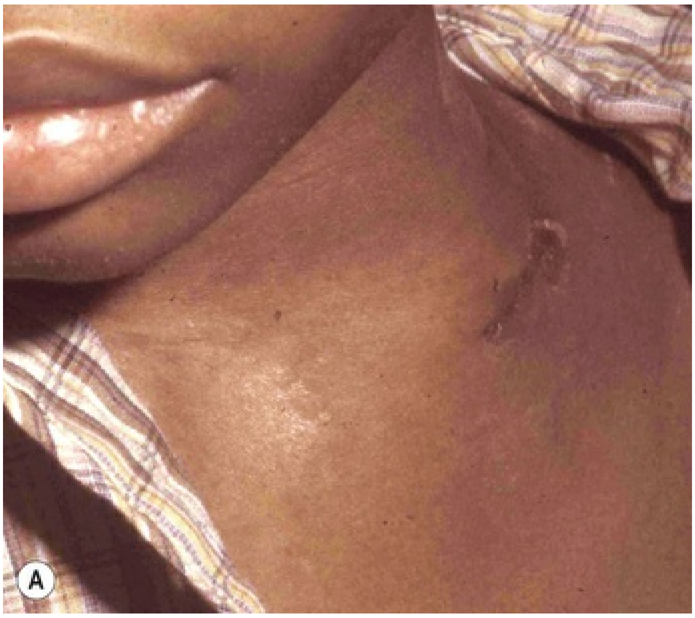

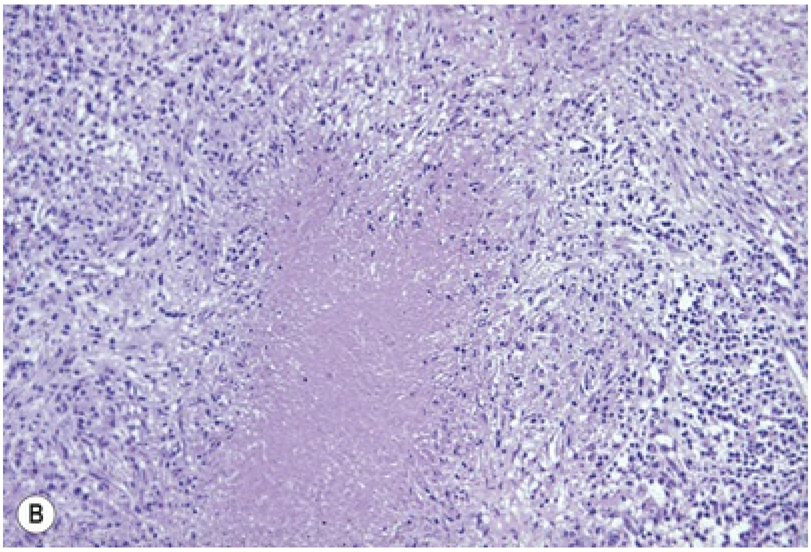

FIGURE 134.6 An adolescent girl had biopsy performed of a supraclavicular mass (A) to exclude lymphoma because of a 1-month history of fever and weight loss and a chest radiograph showing a mediastinal mass. Histology (B) revealed caseous necrosis and granulomatous reaction (400×, hematoxylin and eosin stain). (Courtesy S. S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

The signs and symptoms of pulmonary TB in children usually are minor and occur more commonly in children younger than 5 years of age.[65,66] Infants most frequently manifest nonproductive cough and mild dyspnea. Fever, night sweats, anorexia, and irritability are less common. Some infants have failure to thrive, which may not improve until months after initiation of appropriate chemotherapy. Tachypnea, localized wheezing, or decreased breath sounds can occur with bronchial obstruction, but respiratory distress is rare.[67,68] Nonspecific signs and symptoms occasionally resolve after antibiotic therapy for more common bacterial pneumonias; this occurrence suggests superinfection distal to nodal obstruction.

Progressive pulmonary TB, a rare but serious complication, occurs when the parenchymal focus enlarges and develops a large caseous center. The clinical course and radiographic appearance can resemble those of acute bacterial pneumonia (Fig. 134.7).[69–71] Common findings include hyperpyrexia, moderate to severe cough, night sweats, dullness on chest percussion, rales, and decreased breath sounds over the affected area. Central liquefaction can produce a thin-walled cavity, which can cause rupture into the pleural space (i.e., causing a bronchopleural fistula or pyopneumothorax) or the pericardium (i.e., causing acute pericarditis with or without constriction). Before the advent of chemotherapy, 30% to 50% of children with progressive pulmonary TB died. With current treatment, the prognosis is excellent for full recovery.

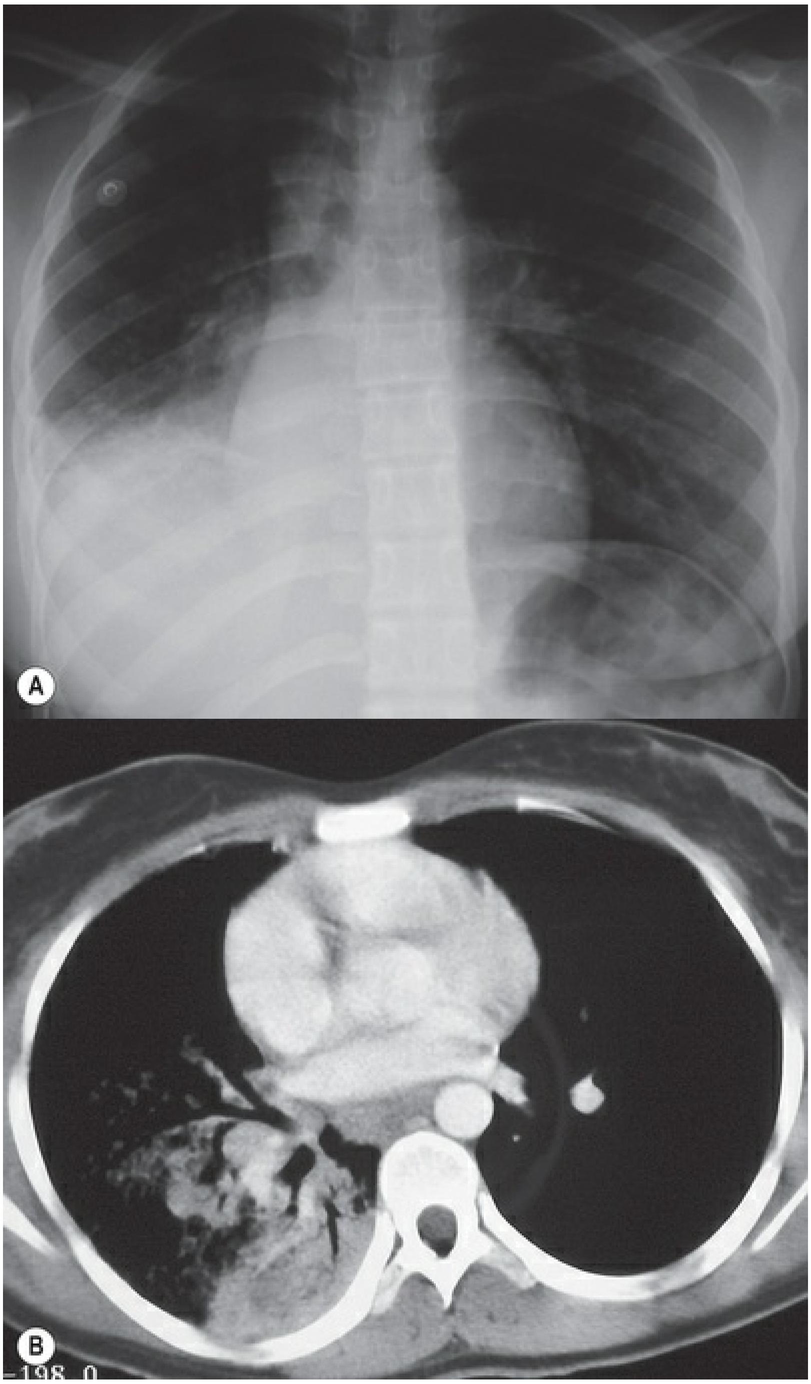

FIGURE 134.7 Pulmonary tuberculosis with hemoptysis. (A) Chest radiograph shows right lower-lobe consolidation. Bronchoscopy revealed hemorrhage and a large clot obscuring lumen to the

right lower lobe. Computed tomography showed multiple nodes abutting airways and consolidation and atelectasis of the right lower lobe. A hilar node and the most rostral lower lobe infiltrate are shown (B). Bronchoalveolar lavage was smear negative but culture positive for *Mycobacterium tuberculosis.* (Courtesy S. S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Older children can have reactivation (adult-type) pulmonary TB.[41,72–76] This occurs more frequently when infection is acquired after 7 years of age, especially at the onset of puberty.[40,72] Common symptoms include fever, anorexia, weight loss, night sweats, productive cough, chest pain, and hemoptysis. Physical examination findings usually are minor or absent, but the radiographic appearance is disproportionately abnormal (e.g., extensive upper lobe infiltrates, upper lobe cavities with or without calcification) (Fig. 134.8). Reactivation infection usually remains localized to the lungs. Most signs and symptoms improve within several weeks of the start of effective treatment, although cough can linger for several months.

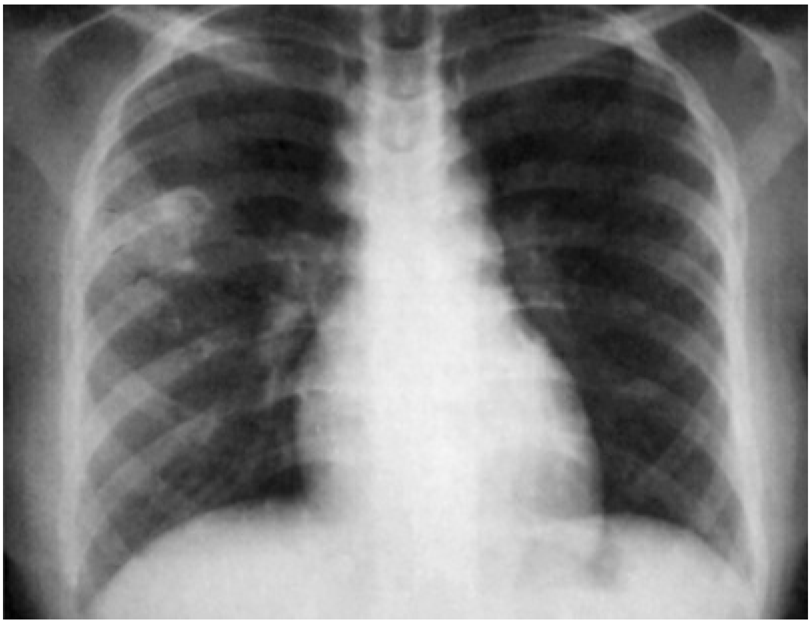

FIGURE 134.8 Multiloculated cavity with calcification in right upper lobe due to adult-type tuberculosis.

Pleural Disease

Pleural TB is caused by the hypersensitivity response to the discharge of a few bacilli from a subpleural focus into the pleural space.[77] Occasionally, a larger discharge causes a unilateral generalized pleural effusion, which usually occurs within 6 to 9 months of initial infection.[78] Pleural TB is not associated with segmental pulmonary lesions and only rarely is associated with miliary TB. Symptoms usually begin abruptly and consist of fever, chest pain, and shortness of breath. Examination reveals dullness to percussion and diminished breath sounds on the affected side. Fever often is high and persists for several weeks despite effective treatment.[79]

Pleural membrane biopsy is the most valuable diagnostic procedure because histopathologic examination demonstrates caseating granulomas in up to 90% of cases and tissue culture is positive in up to 70% of cases. Acid-fast smear of pleural fluid usually is negative; pleural fluid culture is positive in 30% to 50% of cases. Pleural fluid typically is yellow and occasionally is blood tinged, with a specific gravity of 1.012 to 1.025, protein level of 2 to 4 g/dL, glucose level of 20 to 40 mg/dL, and white blood cell count of 100 to 1000 cells/mm^3. Cells classically are predominantly neutrophils early, followed by a high proportion of lymphocytes.

Cardiac Disease

Occurring in 1% to 4% of childhood TB cases, pericarditis is the most common form of cardiac TB.[80] In approximately 10% to 20% of cases, fibrosis leads to constrictive pericarditis over a period of months to years. Early symptoms of serofibrinous pericarditis are nonspecific and usually consist of low-grade fever, malaise, weight loss, and cough; in children, chest pain is unusual. Examination can reveal a pericardial friction rub, distant heart sounds, and pulsus paradoxus. Initially, pericardial fluid is serofibrinous or slightly hemorrhagic; it rarely stains positive for AFB but yields a positive culture in 30% to 70% of cases. Pericardial biopsy shows caseating granulomas in 50% to 75% of cases, and culture usually is positive. The detection of stranding on echocardiography can suggest the diagnosis of TB.[81] The TST result is positive in 75% of cases.

Extrathoracic Disease

Disseminated (Lymphohematogenous) Disease

Clinical manifestations of early bacteremic spread, which occurs in all asymptomatic and symptomatic *M. tuberculosis* infections of the lung, depend on the continual balance between the pathogen and host's immunologic containment. Infants and children with immunosuppression are more likely to have severe forms of disseminated disease.[40,82]

There are three forms of lymphohematogenous TB. The first and most common form is occult dissemination that remains clinically silent or manifests months to years later with metastatic, extrapulmonary TB. The second form is protracted bloodstream infection (rarely seen today), which arises from the intermittent release of bacilli from erosion of a caseous focus into a pulmonary vessel. Protracted bloodstream infection manifests more frequently with indolent, prolonged, intermittent fevers than with acute, spiking fevers. Initial mild pulmonary involvement becomes diffuse after several weeks. Multiorgan involvement is common and often includes hepatosplenomegaly, lymphadenitis of superficial or deep nodes, and appearance of papulonecrotic tuberculids in crops on the skin. Meningitis, which occurs late in the disease course, often was the cause of death in the prechemotherapy era. Gastric aspirate culture often is negative; blood or urine culture can be positive. Bone marrow or liver biopsy yields a high rate of positive stain and culture results.

The third and most common clinically significant form of disseminated TB is miliary disease, which occurs when massive bloodstream infection causes disease in two or more organs.[83–85] Miliary TB most often occurs as an early complication of *M. tuberculosis* infection (i.e., within 2 to 6 months) during infancy or early childhood. However, breakdown of a healed Ghon lesion can lead to miliary spread in older individuals. Clinical manifestations are protean and depend on the number and final location of disseminated organisms.[83] Lesions usually are largest and most numerous in the lungs, spleen, liver, and bone marrow.

The clinical onset of miliary TB usually is indolent, but it can be explosive over several days. Early manifestations consist of malaise, anorexia, listlessness, weight loss, and low-grade fever with normal physical findings. Higher fever, hepatosplenomegaly, and generalized lymphadenopathy develop within several weeks in approximately 50% of children. During this time, the patient has few respiratory symptoms and can have normal chest radiographic findings. A few weeks later, respiratory distress, cough, rales, or wheezing occurs as lungs often become filled with tubercles, and the classic radiographic finding appears (i.e., diffuse lung tubercles resembling millet seeds).[83] If pulmonary disease progresses, alveolar-capillary block can result in respiratory distress, hypoxia, and pneumothorax.

Timely diagnosis of miliary TB requires a high index of suspicion because premortem microbiologic confirmation is achieved in only one third of cases.[85] The highest-yield tests of microbiologic confirmation are acid-fast smear and culture of bone marrow or liver tissue. Gastric aspirate culture usually is negative; blood or urine culture sometimes is positive. Ophthalmologic examination reveals choroid tubercles in 13% to 87% of children.[84–86] Because more than 30% of children with miliary TB have a negative pretreatment TST result, eliciting a history of exposure to an adult with contagious TB is crucial.

The differential diagnosis of miliary parenchymal disease includes lymphocytic interstitial pneumonia in HIV-infected children, histoplasmosis, disseminated neuroblastoma or thyroid carcinoma, and histiocytosis. Headache usually indicates TB meningitis, whereas abdominal pain or tenderness often heralds TB peritonitis.[84,86]

With timely treatment, children with miliary TB have an excellent prognosis. The general sense of well-being improves within 2 weeks of beginning therapy, but resolution of other signs and symptoms lags. For instance, weight gain may not occur for weeks to months, and chest radiograph abnormalities often persist for months.

Lymphatic Disease

TB of the superficial lymph nodes (i.e., scrofula) is the most common form of childhood extrapulmonary TB, accounting for approximately 67% of cases. Historically, scrofula often resulted from drinking unpasteurized cow's milk laden with *M. bovis.* Currently, most cases arise from *M. tuberculosis* acquired by aerosol or droplet nuclei. Supraclavicular, anterior cervical, tonsillar, and submandibular nodes most often are involved due to extension of a

Ghon lesion of the upper lung fields or abdomen. Tuberculous inguinal, epitrochlear, or axillary lymphadenopathy usually results from cutaneous or skeletal TB and rarely occurs in children.

Infected lymph nodes, which enlarge gradually in the early stages, are discrete and firm but not hard or tender. Nodes often feel fixed to underlying or overlying tissues.[87,88] Involvement usually is unilateral but can be bilateral because of crossover drainage of lymphatic vessels in the chest and lower neck. Infection can involve several nodes, resulting in a matted mass. Other than low-grade fever, systemic signs and symptoms typically are absent. The TST result usually is reactive. Although usually present, a Ghon focus is visible radiographically in only 30% to 70% of cases and usually does not cause symptoms. Occasionally, lymphadenitis can progress more acutely, with rapid enlargement associated with high fever, tenderness, and fluctuation. Scrofula rarely manifests as a fluctuant mass with overlying cellulitis.

Distinguishing scrofula from nontuberculous mycobacteria (NTM) lymphadenitis is challenging.[87] Both conditions cause chronic, nontender adenopathy with tissue breakdown or sinus tracts. Chest radiographic findings usually are normal for both infections. If the lymphadenitis is caused by *M. tuberculosis*, the TST induration usually is more than 15 mm; in contrast, NTM usually produce a less intense reaction or no reaction. Two epidemiologic clues—history of exposure to a contagious TB case and the patient's age—can help with the diagnosis. Whereas scrofula occurs in children of all ages, approximately 80% to 90% of NTM lymphadenitis occurs in children younger than 5 years of age.[89,90] Excisional biopsy with culture of the lymph nodes often is required to establish the cause.

Untreated lymphadenitis can resolve but more often progresses to caseating necrosis, capsular rupture, and spread to adjacent nodes and overlying skin, which becomes effaced, shiny, and erythematous (see Fig. 134.6A). Rupture through the skin creates a draining sinus tract, which may require surgical removal.[88]

Central Nervous System Disease

Central nervous system (CNS) TB most commonly manifests as TB meningitis or tuberculoma. TB meningitis complicates 0.5% to 3% of untreated *M. tuberculosis* infection in children and occurs most frequently between the ages of 6 months and 4 years.[91] Occurring 2 to 6 months after initial infection, TB meningitis is rare in infants younger than 4 months of age.

TB meningitis arises from direct invasion during uncontrolled dissemination or from the renewed activity in a caseous lesion in the cerebral cortex or meninges that was established during early, occult lymphohematogenous dissemination.[92–94] Lesions enlarge and discharge small numbers of bacilli into the subarachnoid space. The resulting exudate infiltrates the cortical or meningeal blood vessels, producing inflammation, obstruction, and subsequent infarction of the cerebral cortex. The base of the brain is affected most commonly, accounting for frequent involvement of cranial nerves III, VI, and VII. Exudate can interfere with cerebrospinal fluid (CSF) flow at basilar cisterns, leading to communicating hydrocephalus.[95] The combination of vasculitis, infarction, cerebral edema, and hydrocephalus causes severe brain injury. Hyponatremia and volume expansion due to the inappropriate secretion of antidiuretic hormone commonly occur and contribute to the pathophysiology.[96]

The clinical onset of TB meningitis can be rapid or gradual.[97–103] The disease progresses more quickly among infants and young children, who may have symptoms only for several days before the onset of hydrocephalus, seizures, or cerebral edema. More often, the disease course progresses over several weeks and can be divided into three stages.[104,105] Stage I typically lasts 1 to 2 weeks and is characterized by nonspecific symptoms such as fever, headache, irritability, and drowsiness. Focal neurologic signs are absent, but infants can lose developmental milestones. This stage usually can be recognized as early TB meningitis only in retrospect. Stage II often begins abruptly with lethargy and apathy, nuchal rigidity, a Kernig or Brudzinski sign, seizures, hypertonia, vomiting, cranial nerve abnormalities, and other focal neurologic signs. Some children have signs only of encephalitis, such as disorientation, abnormal movements, and speech impairment. If significant hydrocephalus occurs, early placement of a ventriculoperitoneal shunt or extraventricular device can relieve the symptoms.[106] Stage III is marked by coma, hemiplegia or paraplegia, hypertension, decerebrate or decorticate posturing, progressive vital sign abnormalities, and eventual death.

Microbiologic confirmation of TB meningitis can be difficult. Ideally, CSF should be sampled by lumbar puncture; ventricular CSF often is normal because the pathology occurs distal to the lateral ventricles. The likelihood of microbiologic confirmation directly correlates with the quantity of CSF sampled. Overall rates of positivity for acid-fast stain and culture are 9% and 35%, respectively.[97] In contrast, with at least 10 mL of lumbar CSF, acid-fast stain and culture are positive in up to 30% and 70% of cases, respectively. Other CSF studies, such as nucleic acid amplification tests (NAATs), provide important diagnostic clues, as does microbiologic confirmation of pulmonary TB. The lumbar CSF leukocyte cell count ranges from 10 to 500 cells/mm^3. Neutrophils can predominate early, but lymphocytic predominance is more typical. The CSF glucose level is usually between 20 and 40 mg/dL, but can be less than 10 mg/dL; CSF protein concentration is elevated, sometimes markedly (>400 mg/dL).

Cranial computed tomography (CT) and especially magnetic resonance imaging help establish the diagnosis. Although CT findings can be normal early in the disease, basilar enhancement with communicating hydrocephalus and signs of cerebral edema or focal ischemia can occur later. Magnetic resonance imaging (MRI) is more sensitive and can show widespread areas of focal necrosis, ring enhancement, and edema (Fig. 134.9). Approximately 70% of cases have an abnormal chest radiograph. The TST result is less helpful because it can be nonreactive in up to 45% of cases.[97] History of exposure to or newly identifying a contagious source case is a key diagnostic clue.

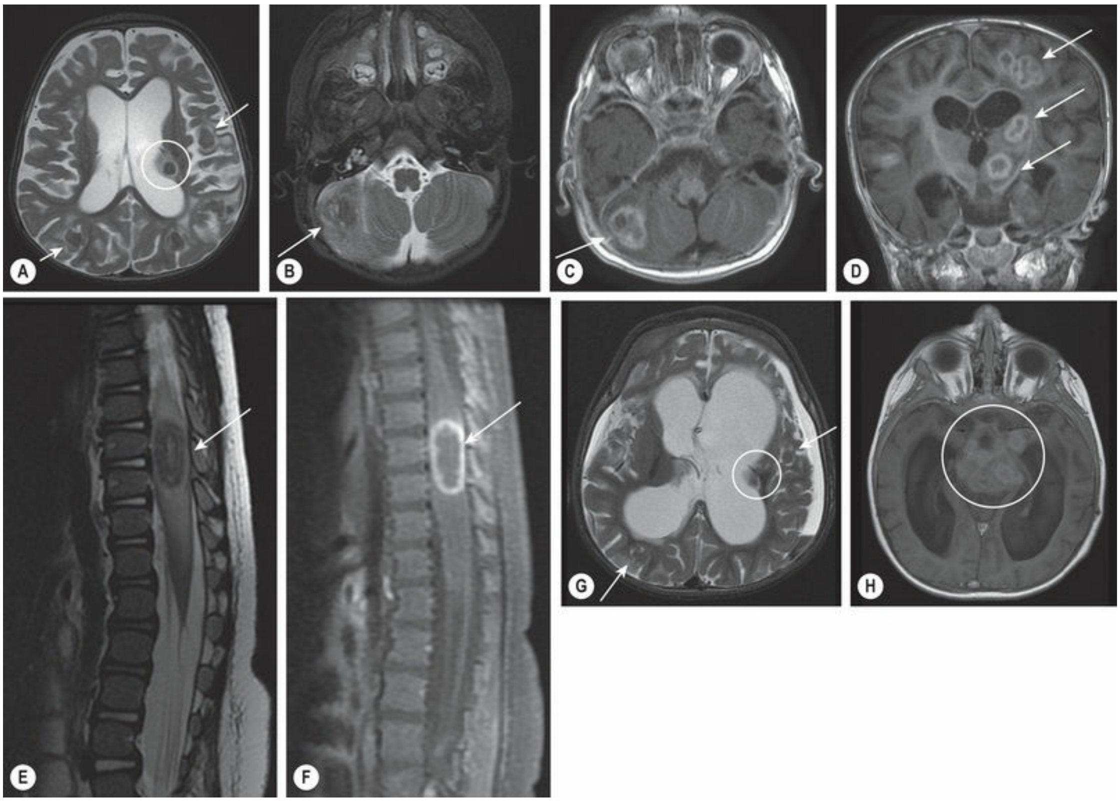

FIGURE 134.9 Tuberculous meningitis in a 6-month-old infant with a 2-week history of lethargy and acute onset of seizures, right facial paralysis, and right-sided hemiparesis. Some representative magnetic resonance images obtained at admission are shown. Axial short tau inversion recovery (STIR) sequence (A) shows ventriculomegaly and multiple bilateral supratentorial T2 hypointense lesions (*arrows* and *circle*). (B) Infratentorial T2 hypointense lesion with surrounding vasogenic edema. Axial postcontrast T1 sequence (C) shows corresponding ring enhancement of lesion in B. Coronal postcontrast T1 sequence (D) shows multiple supratentorial ring enhancing lesions (*arrows*). Sagittal image shows T2 hypointense intramedullary lesion with surrounding vasogenic edema that expands the spinal cord (E). Postcontrast T1 sequence image demonstrates the ring enhancement (F). The patient was given anti-tuberculosis drugs plus corticosteroids and improved. Neurosurgical spinal decompression was performed. Six weeks later, axial STIR sequence shows (G) regression of initial lesions (*arrows* and *circle*) but (H) new nodular lesions within the suprasellar cistern (*circle*). The corticosteroid dose was increased. Drug-susceptible *Mycobacterium tuberculosis* was isolated from gastric aspirates. (Courtesy A. Malik and S. S. Long, St.

Christopher's Hospital for Children, Philadelphia, PA.)

Before the availability of anti-TB drugs, TB meningitis invariably caused death, usually within 3 weeks.[107] Even with current treatment regimens and advanced life-support measures, the disease kills approximately 19% of the children it affects and leaves 54% of survivors with permanent neurologic complications, which include blindness, deafness, paraplegia, and behavioral and intellectual disabilities.[97]

The prognosis for TB meningitis correlates with the clinical stage of illness at the time effective treatment is begun.[97] Patients whose treatment begins in stage I have a 1% risk of death. For patients whose treatment begins in stage II or III, the risks of death increase to 10% and 34%, respectively. The risks of neurologic sequelae are 27%, 41%, and 71% for survivors whose treatment began in stage I, II, and III, respectively.[97]

Because of the diagnostic challenges and poor prognosis associated with TB meningitis, anti-TB treatment should be instituted empirically (while the diagnosis is being established) at least for any child with basilar meningitis accompanied by hydrocephalus, infarction, or cranial nerve involvement with no other apparent cause.

Tuberculoma, another form of CNS infection, usually manifests as a space-occupying lesion and occurs most often in children younger than 10 years of age. The lesion typically is singular and infratentorial and is located at the base of the brain near the cerebellum.[108] Tuberculoma and TB meningitis were once considered distinct entities, but neuroimaging has demonstrated that many young children have both (see Fig. 134.9). Tuberculoma most commonly manifests with headache, fever, and convulsions. The TST result usually is positive, and chest radiographic findings are normal. Although surgical excision is unnecessary, biopsy often is performed for diagnosis.

Paradoxical appearance of tuberculomas during effective therapy for TB meningitis can occur[109,110] (see Fig. 134.9). The pathogenesis of tuberculoma is similar to that of immune reconstitution inflammatory syndrome (IRIS), and the finding does not signify treatment failure. Tuberculoma should be suspected if focal neurologic abnormalities arise or change during treatment of TB meningitis. After consideration of optimized treatment and the possibility of drug-resistant infection, corticosteroid therapy is appropriate, although optimal duration is unclear. Tuberculomas resolve slowly, typically over months to years.

Osteoarticular Disease

Skeletal TB arises from direct lymphohematogenous seeding or extension of a caseous regional lymph node. The interval between infection and clinical manifestations can range from 1 month (i.e., TB dactylitis) to years (i.e., osteoarthritis of the hip). Infection usually begins in the metaphysis. The formation of granulation tissue and caseation can lead to bone necrosis. The bone infection may extend into adjacent soft tissue, leading to abscess formation, or a nearby joint, resulting in articular TB. Often, the infection becomes clinically apparent when the joint becomes involved.

TB most commonly affects weight-bearing bones and joints, especially vertebrae. Spinal TB (i.e., Pott disease) can involve any or multiple vertebral bodies but has a predilection for the lower thoracic or upper lumbar spine. Affected vertebrae usually are contiguous, but there can be skip areas between lesions.[111–113] Vertebral body infection leads to bone destruction and collapse, spondylitis of one or more disk spaces, collapse and wedging of the vertebral body with subsequent angulation of the spine (i.e., gibbus spine), or kyphosis. Infection can rupture into soft tissue, causing paraspinal, psoas, or retropharyngeal abscesses. In children, Pott disease most commonly manifests with low-grade fever, irritability, and restlessness; back pain (usually without significant tenderness); and abnormal positioning or refusal to walk. Rigidity of the spine results from involuntary immobilization and muscle spasm.

Other common sites of skeletal TB include the knee, hip, elbow, and ankle.[114,115] The extent of involvement ranges from mild joint effusion without bone destruction to frank bone destruction and joint restriction due to chronic fibrosis of the synovial membrane. Evolving over months to years, the process most commonly causes mild pain, stiffness, limping, and restrictive movement. The TST result is reactive in 80% to 90% of cases. Culture of joint fluid or bone biopsy usually yields the organism.

TB dactylitis, one form of bony disease, is peculiar to infants. Affected children have distal endarteritis followed by painless swelling of hands or feet and cystic bone lesions. Abscesses are rare. The TST result usually is positive.

Abdominal and Gastrointestinal Disease

TB enteritis, caused by hematogenous dissemination or swallowing of tubercle bacilli discharged from the patient's lungs, most commonly involves the jejunum and ileum near Peyer patches and the appendix.[116–118] Painful shallow ulcers, diarrhea or constipation, and weight loss are typical findings. Mesenteric lymphadenitis usually is prominent. Inflamed nodes can obstruct the intestines or erode through the omentum to cause generalized peritonitis. TB enteritis should be considered as a diagnosis for any child with chronic gastrointestinal complaints and a positive TST result.[119] Diagnosis usually requires biopsy, stain, and culture of lesions.

TB peritonitis is uncommon in adolescents and rare in young children. Generalized peritonitis can result from subclinical or miliary hematogenous dissemination. Localized peritonitis arises from direct extension from an infected intra-abdominal lymph node, an intestinal focus, or TB salpingitis.[120] TB peritonitis typically manifests mild pain and tenderness, ascites, and low-grade fever. The TST result almost always is positive. Rarely, lymph nodes, omentum, and peritoneum become matted and manifest as a palpable, doughy, irregular, nontender mass. Diagnosis is confirmed by paracentesis or biopsy with stains and cultures, but the procedure must be performed with caution to avoid entering fixed bowel intertwined with matted omentum.

Genitourinary Disease

Renal TB rarely occurs in children because the incubation period is at least several years.[121] The disease process begins when tubercle bacilli reach the kidney during lymphohematogenous dissemination, as documented by recovery from urine in disseminated or pulmonary TB. Small caseous tubercles develop in the renal parenchyma and release *M. tuberculosis* into the tubules. A large mass can develop near the renal cortex; this focus of infection discharges large numbers of bacteria through a fistula into the renal pelvis. Infection spreads locally to the ureters, prostate, or epididymis. In early stages, renal TB often is clinically silent except for sterile pyuria and microscopic hematuria.[122] As disease progresses, dysuria, flank or abdominal pain, and gross hematuria can develop. Superinfection frequently occurs and can delay recognition of underlying TB. Ureteral stricture or hydronephrosis complicates the disease.[123] Urine mycobacterial culture results are positive in 80% to 90% of cases, but acid-fast stains of large volumes of sedimented urine are frequently less positive. The TST result usually is positive.

TB of the genital tract is uncommon in both sexes before puberty. Infection usually originates from lymphohematogenous seeding, although it can spread contiguously from the intestinal tract or bone. Adolescent girls can develop hematogenous genital tract TB during the primary infection. Female genital tract TB most often involves the fallopian tubes, followed by the endometrium, ovaries, and cervix. Usual symptoms include lower abdominal pain and dysmenorrhea or amenorrhea. Male genital tract TB typically causes epididymitis or orchitis—manifesting as a unilateral, nodular, painless swelling of the scrotum—and rarely involves the glans penis. Both sexes have a positive TST result, absence of systemic manifestations, and normal chest radiographs. Because unrecognized female genital tract TB can lead to infertility and in vitro fertilization has been associated with congenital tuberculosis, women from endemic regions should have a TST before in vitro fertilization.[124] Suspicion of congenital tuberculosis should rise when mother is from a country with high endemic TB prevalence and she was not tested during infertility evaluation.

Cutaneous Disease

Cutaneous TB, more common decades ago, has four presentations: scrofuloderma, a lesion from direct inoculation, a site of hematogenous dissemination, or a hypersensitivity reaction to the tubercle bacillus.[125] Scrofuloderma occurs when a caseous lymph node ruptures through the skin and leaves an ulcer or sinus tract. Direct inoculation of the skin through an abrasion, cut, or insect bite can cause a small, painless nodule, sometimes with tiny satellite lesions that soon turn into indolent ulcers without surrounding inflammation. Regional lymphadenitis is striking, but systemic symptoms usually are lacking. Direct inoculation also results in verrucosa cutis, a wart-like lesion that appears most commonly on the arms or legs in a person already sensitized to the organism.[126]

Hematogenous dissemination can lead to verrucosa cutis and papulonecrotic tuberculids, which are miliary tubercles in the skin that usually appear as tiny papules appearing most often on the trunk, thighs, and face. The characteristic apple-jelly center of papulonecrotic tuberculids is best demonstrated by covering it with a glass slide. The most common hypersensitivity reaction is erythema nodosum, characterized by large, painful, purple-brown nodules on the shins and extensor forearms.

Congenital Disease

Congenital TB is rare, with fewer than 400 cases reported in the English language literature.[127] The affected infant's mother can have an existing diagnosis of TB, but the mother's disease often is not diagnosed until delivery or later.[128]

Congenital infection depends on the presence and intensity of hematogenous dissemination of *M. tuberculosis* during pregnancy. Placental infection facilitates transmission to the fetus by blood or aspiration of amniotic fluid. However, even massive TB placentitis does not always lead to congenital infection. Congenital infection has been associated with maternal infertility (likely related to fibrosing TB salpingitis) and fetal infection after in vitro fertilization.[124]

In hematogenous congenital TB, *M. tuberculosis* reaches the fetus through the umbilical vein and disseminates widely. If bacilli infect the liver, a primary focus develops with involvement of periportal lymph nodes.[129] Hematogenous primary focus in the fetal lung usually remains dormant until after birth, when oxygenation and circulation increase significantly. Congenital infection of the infant also occurs by aspiration or ingestion of infected amniotic fluid.[130]

Symptoms of hematogenous congenital TB can be present at birth but typically appear by the second or third week of life.[127,128] The most common manifestations are respiratory distress, fever, hepatosplenomegaly, poor feeding, lethargy or irritability, lymphadenopathy, abdominal distention, ear drainage, and skin lesions. Clinical manifestations vary with lesion size and location. Some infants have a normal chest radiograph early in the course, but most have diffuse radiographic abnormalities as disease progresses. More common early radiographic findings are hilar lymphadenopathy and parenchymal infiltrates; approximately 50% of patients have a miliary pattern.

Congenital TB should be suspected in any infant who has sepsis syndrome or other findings compatible with congenital infection with no response to antibiotic therapy and negative evaluation for another congenital infection. Suspicion is high if the mother is at risk for, has, or has had TB.

Timely diagnosis of congenital or neonatal TB is difficult and often is delayed. The initial TST result usually is negative, frequently becoming reactive after 1 to 3 months of therapy. Positive results of acid-fast stains and cultures of body fluids and tissues (e.g., middle ear fluid, tracheal aspirate, bone marrow, lymph node) are needed to confirm the diagnosis.[127] AFB in gastric or tracheal aspirates in a neonate is almost diagnostic because false-positive smear results are rare. Although only 20% of affected children have meningeal involvement, CSF examination and culture should be performed because a diagnosis of TB meningitis would change management. Endometrial specimens from the mother should be obtained because they usually yield positive culture results.

Diagnosis

Tests of Infection

Diagnostic tests for TB detect *M. tuberculosis* in a clinical sample or the host's immune response to the organism. TB diagnosis is complicated by the need to distinguish between asymptomatic infection and clinically significant disease. Current tests of infection, the TST and interferon γ release assays (IGRAs), are immune based and cannot discriminate between infection and disease.

Tuberculin Skin Test

The definitive TST uses 5 tuberculin units of purified protein derivative (PPD) stabilized in Tween 80. A 26- or 27-gauge needle and a graduated syringe are used to inject 0.1 mL of PPD intradermally into the volar surface of the forearm; the immediate appearance of a wheal indicates correct technique.[131] The delayed hypersensitivity reaction to the TST usually peaks at 48 to 72 hours.

In some people, reaction occurs after 72 hours and should be measured. It may take up to 10 weeks after infection occurs for an immunocompetent individual to react to the TST.

For accuracy, the TST result should be interpreted by trained healthcare providers. The diameter of induration—not erythema—is measured perpendicular to the axis of administration and recorded in millimeters. TST result should not be recorded as simply positive or negative. An allergic or Arthus-like reaction to TST components can cause erythema and induration within hours after application, peaking as late as 24 hours (for the Arthus reaction) and beginning to wane at 48 hours; these findings do not indicate *M. tuberculosis* infection.

A nonreactive TST result does not exclude *M. tuberculosis* infection or disease because a variety of factors can lower tuberculin reactivity (Box 134.2).[132] Approximately 10% of immunocompetent children with culture-confirmed TB disease do not react at first to the TST.[133] Most of these children have a positive test result after several months of treatment, suggesting that TB was acquired recently or that untreated disease depressed specific immune responses. Patients with immunocompromise due to a variety of causes, including disseminated TB and age younger than 6 months, often are anergic (i.e., have diminished cellular response to multiple stimuli).[134] The measles vaccine can suppress TST response transiently. This suppression does not occur when the TST is done on the same day as measles vaccination. However, if the vaccine has already been administered, the TST should be delayed until 4 to 6 weeks after immunization unless the clinician is evaluating the child for recent exposure or TB disease. Due to theoretic concerns, this recommendation extends to other live viral vaccines.[135] Improper storage, dilution, placement, and interpretation of the TST can cause false-negative results.

Box 134.2

Factors That Cause Decreased Response to Tuberculin Skin Test

Host-Related Factors

Infection

- Viral (rubella, rubeola, varicella, influenza)

- Bacterial (typhoid fever, brucellosis, leprosy, pertussis, overwhelming tuberculosis)

- Fungal (blastomycosis)

Live virus vaccines

Chronic renal failure

Malnutrition

Diseases affecting lymphoid organs (leukemia, lymphoma, human immunodeficiency virus infection)

Immunosuppressive drugs (corticosteroids, antineoplastic agents)

Age (infants <6 months of age and elderly)

Stress (surgery, burns, mental illness)

Tuberculin-Related Factors

Improper storage (exposure to light or heat)

Improper dilution

Chemical denaturation

Contamination

Adsorption to glass or plastic

Administration-Related Factors

Incomplete injection of test dose

Delayed administration after loading syringe

Injection given subcutaneously

Reading-Related Factors

Inexperienced reader (should measure induration only)

Conscious or unconscious bias

Error in recording

The most significant causes of false-positive TST reactions are recent NTM infection and prior bacille Calmette-Guérin (BCG) vaccination.[136–138] NTM infection, which occurs more frequently near the equator, usually causes a cross-reaction of 10 mm or less (but can be larger); cross-reactivity can last for several months. In studies of BCG-vaccinated newborns, only 50% have a positive TST result, and 80% to 90% lose the reactivity within 5 years. Children or adults who receive BCG have higher initial and longer responses to TST, but most lose tuberculin reactivity within 10 years of vaccination.[139] The degree of reactivity also is affected by BCG product and nutritional status.[136,138] TST reactivity after BCG vaccination is expected to measure less than 10 mm of induration at 48 to 72 hours, although reactions of 10 to 15 mm can occur.

Prior BCG vaccination is not a contraindication to tuberculin testing. In the United States, the TST result usually is interpreted similarly for persons with or without a history of vaccination.[18] Countries that use BCG vaccine frequently have high rates of endemic TB, and studies have demonstrated that a positive TST result for a previously BCG-vaccinated child who is a close contact with an active TB case likely represents *M. tuberculosis* infection.[137,140]

Three cutoff values are used to interpret TST reactivity. The cutoff values represent a statistical attempt to minimize false-positive or false-negative readings and vary according to individual and epidemiologic factors, of which exposure to *M. tuberculosis* is the most heavily weighted (Box 134.3). For children at highest risk for infection progressing to disease, an induration diameter of ≥5 mm is classified as a positive result. For other high-risk groups, an induration diameter ≥10 mm is a positive result. For low-risk children, an induration diameter ≥15 mm is a positive result.

Box 134.3

Interpretation of Tuberculin Skin Test as Positive by Diameter of Induration and Risk

Category[a]
Induration ≥5 mm in Diameter
Contact with an infectious case
Abnormal chest radiograph
Human immunodeficiency virus infection
Immunosuppression from any cause
Induration ≥10 mm in Diameter
Birth in a tuberculosis high-prevalence country
Frequent exposure to high-risk adults[b]
Illicit intravenous drug use
Other medical risk factors[c]
Work in healthcare field
Member of a locally identified high-risk population
Age ≤4 years
Induration ≥15 mm in Diameter
Regardless of age or risk factors

---

[a] Single risk factor in a category is sufficient.

[b] Such as individuals who are HIV-infected, homeless, users of illicit drugs, residents of nursing homes, incarcerated or institutionalized, or migrant farm workers.

[c] Such as Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure, and malnutrition.

In the United States, it is preferable to screen children for *M. tuberculosis* infection risk factors with a questionnaire. The test of infection is performed only if there are risk factors.[141]

Interferon γ Release Assays

QuantiFERON-TB Gold (QFT, Cellestis/Qiagen, Carnegie, Australia) and T-SPOT-TB (T-SPOT, Oxford Immunotec, Abingdon, UK) are the two commercially available IGRAs. In terms of performance, neither test is preferred.[132] IGRAs measure IFNγ secreted by the patient's T lymphocytes (QFT) or the number of IFNγ-secreting lymphocytes (T-SPOT) on ex vivo stimulation with *M. tuberculosis*-specific antigens that are not found in BCG vaccines or most NTM species (except *M. marinum*, *M. kansasii*, *M. szulgai*, and *M. flavescens*). Both IGRAs use positive and negative controls; if either control fails, the result is deemed indeterminate (QFT) or invalid (T-SPOT).

Like the TST, IGRAs produce continuous results, and cutoff values are used to interpret results as positive or negative. For T-SPOT only, an intermediate result is classified as borderline. Unlike the TST, each IGRA has only one cutoff value regardless of the patient's exposure history or immune status. However, multiple studies have questioned this lack of risk stratification and suggest a need for further refinement of IGRA cutoff values.[142–148]

Pediatric studies have demonstrated that IGRAs have a higher specificity than the TST for TB infection, particularly in settings of low TB burden and among BCG-vaccinated children.[149–152] One meta-analysis estimated a specificity of 90% to 100% for IGRAs, compared with 56% for the TST.[152] IGRAs and the TST have comparable sensitivities of 75% to 90% in immunocompetent individuals.[149–152] However, like the TST, IGRAs have poor sensitivity among immunocompromised hosts and cannot differentiate TB infection from disease.[153–157] A lack of data on IGRA performance in children younger than 5 years of age has prompted hesitancy to use these assays in this age group.[132] In contrast, the TST is routinely used in children as young as 6 months of age.

Recommendations for Tests to Diagnose Tuberculosis Infection

In high-income countries, a TST or IGRA may be used to diagnose TB infection in children at least 5 years of age. For children younger than 5 years of age, TSTs are preferred, although some experts use an IGRA for children 2 years or older, particularly if they have received BCG and have no significant TB risk factors.

An IGRA can be used to confirm TB infection in a BCG-vaccinated child who has a positive TST result. Alternatively, an IGRA can be used in lieu of the TST for the initial evaluation. However, exposure to a contagious TB patient is the most important consideration in the interpretation of tests of infection. A positive TST result in a BCG-vaccinated child recently exposed to a person with contagious tuberculosis is most likely a true positive, and confirmation with an IGRA is not recommended.

Because of their imperfect sensitivities, negative tests of infection cannot rule out TB disease and must be interpreted in concert with epidemiologic, clinical, and radiographic data.[132] Some experts may use the TST and both IGRAs to maximize sensitivity in an immunocompromised child suspected of having TB disease. The WHO recommends against IGRA use in high-burden, resource-limited settings because IGRAs are more expensive than the TST, require greater laboratory infrastructure, and do not substantially improve diagnostic sensitivity.[158]

Microbiologic Confirmation and Drug Susceptibility Testing

Methods of Specimen Collection

Expectoration is the preferred specimen collection method for children who can produce sputum. However, for young children who cannot expectorate, other approaches are used to collect respiratory specimens. While a child sleeps, mucociliary transport sweeps respiratory secretions up the airways into the throat. The child swallows these secretions into the stomach.

Gastric aspiration attempts to collect these swallowed respiratory secretions. To minimize the chance of stomach emptying, the procedure should be performed as early in the morning as possible, and the child should abstain from eating or drinking for the preceding 8 hours. The procedure begins with nasogastric tube insertion. If lubrication is required, sterile water or the patient's own saliva should be used; commercially available lubricants can be bactericidal. The stomach contents should then be aspirated. If less than 10 mL of material is aspirated, 5 to 10 mL of normal saline should be injected through the tube, left for 2 to 3 minutes, and then aspirated and added to the first collection. Because the tubercle bacilli do not tolerate gastric acidity, the sample should be neutralized immediately. Concentration, decontamination, and culture also should be performed as soon as possible after collection. To optimize diagnostic yield, gastric aspirates should be performed on 3 consecutive mornings.[159,160]

Sputum induction, an alternative to gastric aspiration, works by increasing the child's tussive force. Sputum induction requires the child to fast for 3 hours before the procedure. A 5-mL solution of 3% hypertonic saline is administered by nebulization with a flow of 6 to 8 L/min. Children with a history of airway reactivity may benefit from premedication with a β-agonist, which decreases the risk of bronchospasm. For infants and young children who cannot expel the resulting sputum, trained personnel must suction out the oropharynx to collect the specimen; two or three samples are recommended to increase diagnostic yield.[160] Most studies demonstrate a lower yield of *M. tuberculosis* from bronchoalveolar lavage specimens compared with properly obtained gastric aspirates.[161–163]

Methods of Microbiologic Confirmation and Drug Susceptibility Testing

Tests of microbiologic confirmation are divided into genotypic tests, which detect nucleic acid fragments from *M. tuberculosis*, and phenotypic tests, which detect whole microbes or their components. The sensitivity of both methods depends on bacterial burden and is therefore low for children due to the paucibacillary nature of childhood disease. Drug susceptibility testing (DST) methods also are characterized as phenotypic or genotypic. Phenotypic DST evaluates the strain's growth or metabolic activity in the drug's presence, and genotypic DST detects resistance-conferring mutations.

Conventional Approach.

The conventional approach consists of acid-fast stain and microscopy, mycobacterial culture, and the proportion method for DST. Acid-fast microscopy and mycobacterial culture have low sensitivity for detecting *M. tuberculosis*. Even with optimal specimen collection and laboratory processing, only 10% to 15% of children with clinically suspected pulmonary TB have smear-positive samples, and only 30% to 40% have culture-positive samples.[160,164,165] Microbiologic confirmation of extrapulmonary TB also is elusive.[44,97,166,167] For example, the proportions of smear-positive and culture-positive CSF samples for children treated for TB meningitis are approximately 9% and 35%, respectively.[97]

The proportion method for DST, which is the gold standard, can be performed only if *M. tuberculosis* has been isolated in culture. To perform the test, a critical concentration of each drug is placed in media with standardized inoculum. Resistance is diagnosed if the proportion of resistant bacilli exceeds 1%. The proportion method is performed routinely with more than one critical concentration of isoniazid—a clinically significant practice because higher concentrations (doses) of the drug may overcome low-level resistance. Different levels of isoniazid resistance correlate with specific genetic mutations; genotypic DSTs assess for different levels of isoniazid resistance by detecting the corresponding mutations. The proportion method lacks standardized techniques and interpretations for ethambutol, pyrazinamide, and second-line drugs.[168]

Obtaining a positive culture on solid media, such as Löwenstein-Jensen or Middlebrook agar, often requires 4 to 6 weeks, followed by an additional 2 to 4 weeks for DST. Automated liquid media systems have shortened the time to positivity to 1 to 3 weeks but have not increased culture sensitivity. Use of an automated liquid media system for the proportion method shortens time to result to 1 week.

Nucleic Acid Amplification.

Several NAATs for mycobacteria have been developed with various target sequences, assay formats, and specimen-processing procedures.[169–177] Most NAATs use the insertion element IS6110 to detect *M. tuberculosis*.[174]

Xpert MTB/RIF (Xpert), the most widely used NAAT, uses an automated, cartridge-based polymerase chain reaction (PCR) platform and probes to detect in 2 hours the presence of *M. tuberculosis* and mutation of *rpoB*, the gene responsible for most rifampin resistance. Because rifampin resistance rarely occurs in the absence of isoniazid resistance, detection of a *rpoB* mutation serves as a proxy for the diagnosis of MDR-TB. Compared with culture, a meta-analysis showed that the Xpert overall sensitivity was only 66% for respiratory samples from 2600 children.[178] In stratified analyses, Xpert had a sensitivity of 95% for AFB smear-positive samples but only 55% to 62% sensitivity for AFB smear-negative, culture-positive samples.[178] HIV status and specimen type (i.e., sputum or gastric lavage) did not affect assay performance.[178] Taken together, Xpert appears to be more sensitive than sputum smear microscopy but less sensitive than culture for confirming childhood pulmonary TB.

Few reports have described Xpert's diagnostic utility for childhood extrapulmonary TB. In a large cohort study that used culture as the reference standard, Xpert demonstrated sensitivities of 100% and 75% for lymph node tissue and CSF, respectively.[179] In other studies that included children but did not disaggregate pediatric results, sensitivities ranged between 50% and 100% for both CSF and lymph node tissue.[178,180–182] Xpert has demonstrated 95% or higher sensitivity and specificity for rifampin resistance, but false-positive results can result from the detection of silent *rpoB* mutations that do not affect phenotypic susceptibility.[178,183,184]

The line probe assay (LiPA), another NAAT, uses PCR to isolate and amplify genes with resistance mutations. LiPAs, which can be performed on patient samples or culture isolates, produce results in 1 to 2 days. Numerous LiPA models are commercially available and vary in the mutations detected. The newest models detect resistance to ethambutol and drugs used to treat MDR-TB. LiPAs have 98% or higher sensitivity and specificity for rifampin resistance. Although specificity for isoniazid resistance is consistently high, sensitivity varies with the LiPA model and ranges from 57% to 100%.[185,186]

Genetic Sequencing.

DNA sequencing, which has been used to identify *M. tuberculosis* strains for epidemiologic purposes, has been adapted for DST. Unlike NAATs, which use probes to detect a set number of resistance-conferring mutations fixed a priori into the product design, sequencing platforms can identify all possible mutations in target genes and be rapidly modified to add more genes. Sequencing can also distinguish between silent and phenotypically significant mutations. Studies have shown more than 90% sensitivity and specificity for isoniazid resistance and more than 95% sensitivity and specificity for rifampin resistance.[184,187–189]

Recommendations for Diagnosing Tuberculosis Disease and Drug Resistance

The diagnostic approach for TB disease in children varies according to the patient's clinical presentation and the available technology. Guiding principles include the following:

1. Although microbiologic confirmation of childhood TB disease is difficult, most cases can be diagnosed clinically. All children suspected of having TB should undergo a careful history, including identification of possible source cases, physical examination (including growth assessment), test of infection (i.e., TST or IGRA), and relevant radiologic exams (e.g., chest radiography for pulmonary disease, neuroimaging for TB meningitis). Each of these elements may provide important diagnostic clues.

2. In most cases of suspected childhood TB, microbiologic confirmation should be pursued with culture, which remains the most sensitive diagnostic tool. For children with a known source case, a positive test result for infection, and classic radiographic findings, microbiologic testing may not be necessary as long as the source case has a DST result that can guide treatment.

3. Although less sensitive than culture, molecular methods may shorten the time to microbiologic confirmation and diagnosis of drug resistance. Diagnostic speed is particularly important in instances of severe, life-threatening disease or in areas with high drug-resistant TB prevalence, particularly when no source case DST is available to guide therapy. When available, both culture and molecular testing should be obtained to increase diagnostic yield.[190] Molecular methods also should be applied to known source cases to ensure timely initiation of appropriate therapy for themselves and

their child contacts.

4. In the United States and other countries with a low prevalence of rifampin resistance, the detection of rifampin resistance by Xpert should be confirmed with phenotypic DST or sequencing.[191] The diagnosis of MDR-TB should trigger testing for resistance to second-line drugs. In the United States, the Centers for Disease Control and Prevention (CDC) offers expanded DST through its Molecular Detection of Drug Resistance service, which employs sequencing methods.[192]

Therapy

Antituberculosis Agents

Anti-TB drugs are bacteriostatic or bactericidal (Table 134.2). Isoniazid, rifampin, pyrazinamide, and ethambutol are the first-line agents for adults and children.

TABLE 134.2

Antituberculous Drugs Used for Children

Drug	Dosage Forms	Daily Dosage for Treatment of Infection or Disease (mg/kg/day)	Twice- or Thrice-Weekly Dosage for Treatment of Infection or Disease (mg/kg/dose)	Maximum Dose
Isoniazid[a]	Scored tablets • 100 mg • 300 mg Syrup • 50 mg/5 mL[b] • 100 mg/5 mL[b]	10–20 (PO)	20–30	Daily: 300 mg Intermittent: 900 mg/dose
Rifampin[a]	Capsules • 150 mg • 300 mg Syrup formulated from capsules[c] Aqueous solution for IV injection	10–20 (PO or IV)	10–20	Daily: 600 mg Intermittent: 600 mg/dose

Pyrazinamide	Scored tablets • 500 mg	20–40 (PO)	50–70	2 g
Streptomycin	Vials • 1 g • 4 g	20–40 (IM or IV)	20–40 (IM or IV)	1 g
Ethambutol	Scored tablets • 100 mg • 400 mg	20 (PO)	50	2.5 g
Ethionamide	Tablets • 250 mg • 1 g	10–20 (PO)	No data to support intermittent dosing	1 g
Amikacin	Vials • 500 mg • 1 g	15 (IM or IV)	15–25 (IM or IV)	1 g
Kanamycin	Vials • 75 mg/2 mL • 500 mg/2 mL • 1 g/3 mL	15 (IM or IV)	15–25 (IM or IV)	1 g
Capreomycin	Vials • 1 g	15–30 (IM or IV)	15–30 (IM or IV)	1 g
Cycloserine	Capsules • 250 mg	10–20 (PO)	No data to support intermittent dosing	1 g
***p*-Aminosalicylic acid**	Granule packets • 3 g	200–300 divided bid (PO)	No data to support intermittent dosing	10 g
Levofloxacin	Tablets • 250 mg • 500 mg • 750 mg Vials • 25 mg/mL	15–20 (PO or IV)	No data to support intermittent dosing	1 g
Linezolid[e]	Tablets • 400 mg • 600 mg IV solution	10 mg (once daily ≥12 yr; divided bid <12 yr of age)	No data to support intermittent dosing	300 mg

[a] Rifamate is a capsule containing 150 mg of isoniazid and 300 mg of rifampin. Two capsules provide the usual adult (≥50 kg) daily dose of each drug. Rifater is a tablet containing 50 mg of isoniazid, 120 mg of rifampin, and 300 mg of pyrazinamide. Neither combination has been studied in children, and neither is available in a pediatric formulation.

[b] Many experts recommend avoidance of isoniazid syrup because it is unstable and is associated with frequent gastrointestinal complaints, especially diarrhea.

[c] Merrell Dow Pharmaceuticals (Cincinnati, OH) issues directions for preparation of this extemporaneous syrup.

[e] Dosing recommendations from Garcia-Prats AJ, Rose PC, Hesseling AC, Schaaf S. Linezolid for the treatment of drug-resistant tuberculosis in children: a review and

recommendations. Tuberculosis (Edinb) 2014;94:93–104.

[d] Total adult daily dosage. Fluoroquinolones can cause gastrointestinal disturbance, rash, and headache. In theory, they damage growing cartilage, but in practice, this reaction is rarely observed.

Isoniazid.

Isoniazid, the most widely used anti-TB medication, is bactericidal, easily administered, inexpensive, and relatively nontoxic in children. Isoniazid is almost completely absorbed from the gastrointestinal tract, and the recommended dose achieves therapeutic levels in all body tissues and fluids, including the CSF. In adults, isoniazid has been associated with symptomatic deficiency of pyridoxine, which is mainly found in milk and meat. However, in pediatrics, this effect occurs almost exclusively in malnourished or HIV-infected children.[193] Pyridoxine supplementation (25 to 50 mg/day) is not usually necessary in otherwise healthy, well-nourished children but is recommended for exclusively breastfed infants, HIV-infected children, pregnant adolescents, and children and adolescents with meat- and milk-deficient diets.

The major toxicity of isoniazid is hepatitis. Almost 10% of children develop transiently elevated serum alanine aminotransferase (ALT) levels while taking isoniazid, but clinical toxicity is rare. Most children are followed clinically without serum biochemical monitoring, and ALT levels usually return spontaneously to normal without interruption of treatment.[194] Isoniazid can interact with several other drugs and can increase serum phenytoin levels by blocking its metabolism in the liver, leading to toxicity.[195,196] A dose of isoniazid exceeding 15 mg/kg/day or in combination with rifampin enhances toxicity.[197]

Rifampin.

Rifampin is bactericidal for *M. tuberculosis* and generally well tolerated at a dose of 15 mg/kg/day. Rifampin belongs to the rifamycin class of antibiotics. This class also includes rifabutin and rifapentene; the latter has a long half-life that allows for weekly administration. Although 75% of rifampin is protein bound, it penetrates well into most tissues and fluids except the CSF. Despite rifampin's only modest CSF penetration—which improves in the setting of inflammation—its use has been associated with improved outcomes of childhood TB meningitis.[198]

Gastrointestinal upset is rifampin's most common side effect. Other adverse events include skin eruptions, hepatitis, and occasional thrombocytopenia or cholestatic jaundice.[193] Rifampin is excreted in bodily fluids and causes urine and stool to turn orange. Discoloration of tears may cause orange staining of contact lenses. This body fluid discoloration serves as a useful indicator of treatment adherence. Rifampin lowers the effectiveness of oral contraceptives and accelerates excretion of some hepatically metabolized drugs including HIV protease inhibitors.

Pyrazinamide.

Pyrazinamide is bactericidal for *M. tuberculosis*, particularly when bacilli are found inside macrophages or other similarly acidic environments. Pyrazinamide exerts maximal effect during the first 2 months of therapy, and its use allows treatment duration to be shortened to 6 months.[199] Pyrazinamide is well absorbed from the gastrointestinal tract and penetrates most tissues, including CSF.[200,201]

The optimal dose in children has not been established because of a lack of pharmacokinetic data. In children, hepatotoxicity occurs infrequently at the standard daily dose of 30 to 40 mg/kg but is more common with higher doses.[202] Nonetheless, pyrazinamide causes hepatitis more often in children than does isoniazid or rifampin, particularly when given with rifampin. Adults taking pyrazinamide can experience symptomatic hyperuricemia with arthralgia, arthritis, and overt gout; children rarely experience these symptoms. Other adverse events include gastrointestinal upset, rashes, and intense pruritis.[193]

Ethambutol.

Ethambutol is administered, easily absorbed well, and bacteriostatic against *M. tuberculosis*. Ethambutol has poor CSF penetration, even in the setting of inflammation.[198,203,204] Ethambutol primarily is used as the fourth drug when there is a possibility of resistance to other first-line drugs.

The most serious adverse effect is retrobulbar neuritis, which appears to be dose related and manifests with blurred vision, central scotoma, and red-green color blindness.[193] At the standard daily dose of 20 mg/kg, neuritis is rare in children and all patients with normal renal function.[205] A child's inability to cooperate with vision testing or report visual changes should not preclude ethambutol use.

Second-Line Agents.

Mostly used to treat MDR-TB, second-line agents may be useful for drug-susceptible disease in patients with CNS TB, a contraindication to first-line drugs, or a decreased ability to tolerate or absorb enteral medications (Table 134.3). Ethionamide and fluoroquinolones cross the blood-brain barrier well and appear to be effective for CNS TB.[103,198,206] Amikacin, kanamycin, and streptomycin have some ability to penetrate the CNS and may be used as the fourth drug, but dose-dependent ototoxicity and nephrotoxicity may limit their use. For patients who cannot tolerate or absorb enteral drugs, rifampin, amikacin, kanamycin, streptomycin, capreomycin, fluoroquinolones, and linezolid have parenteral formulations.

TABLE 134.3

Regimens for Treatment of Tuberculosis Infection

Drugs	Duration (mo)	Pediatric Dose	Frequency	Total Doses	Contraindications
Isoniazid	9	10–15 mg/kg; 300 mg maximum	Daily	270	Source case with isoniazid resistance
		20–30 mg/kg; 900 mg maximum	Twice or thrice weekly[a]	76	
Isoniazid *plus* rifapentine	3	Children ≥2 yr old: Isoniazid[b]: 15 mg/kg rounded up to the nearest 50 or 100 mg; 900 mg maximum Rifapentine[b]: 10.0–14.0 kg, 300 mg 14.1–25.0 kg, 450 mg 25.1–32.0 kg, 600 mg 32.1–49.9 kg, 750 mg ≥50.0 kg, 900 mg maximum	Once weekly[a]	12	Source case with isoniazid or rifampin resistance; child with HIV infection receiving antiretroviral therapy; pregnancy; age <2 yr
Rifampin	4[c]	10–20 mg/kg; 600 mg maximum	Daily	120	Source case with rifampin resistance; child with HIV infection receiving antiretroviral therapy

Isoniazid *plus* rifampin	3	Isoniazid: 10–20 mg/kg; 300 mg maximum Rifampin: 10–20 mg/kg; 600 mg maximum	Daily	90	Source case with isoniazid or rifampin resistance; child with HIV infection receiving antiretroviral therapy

[a] Intermittent regimens must be provided by directly observed therapy (DOT).

[b] Isoniazid is formulated as 100-mg and 300-mg tablets. Rifapentine is formulated as 150-mg tablets in blister packs that should be kept sealed until use.

[c] Some experts recommend 6 months of daily rifampin (180 doses); the American Academy of Pediatrics endorses both the 6-month and the 4-month regimens.

Optimal doses and dosing intervals for second-line agents have not been established for the treatment of childhood TB. Moreover, child-friendly formulations do not exist for most second-line agents. Second-line agents usually have less efficacy and greater toxicity, and they should be used only in consultation with a TB expert.

Principles of Approach to Antimicrobial Regimens

Success of antimicrobial therapy against *M. tuberculosis* depends on antimicrobial susceptibility, bacillary number and activity level, and location of the organisms (e.g., open cavities, closed caseous lesions, within macrophages). The high oxygen tension and low pH in open cavities allows *M. tuberculosis* to grow to a density of more than 10^9 organisms. Reactivation TB is associated with a high density of organisms at all three sites. Most young children with pulmonary TB are infected with a smaller number of organisms because they do not have cavitary lesions.

Any large population of a single *M. tuberculosis* strain has individual bacilli resistant to a particular antibiotic, even if the strain responds clinically to that drug.[207] This phenomenon occurs because *M. tuberculosis* drug resistance mutations occur at predictable frequencies: for streptomycin, mutations per organism occur at a density of 10^{-6}; for ethambutol, 10^{-7}; for isoniazid, 10^{-6} to 10^{-7}; and for rifampin, 10^{-8}. A cavity containing 10^9 tubercle bacilli has thousands of drug-resistant organisms, and a closed caseous lesion with 10^6 bacilli has few or none. Fortunately, because the genetic loci for resistance are unlinked on the mycobacterial chromosome, the chance occurrence of resistance to one drug is unrelated to that of any other drug. For a single bacillus to have primary drug resistance to two drugs, it would require a density of 10^{11} to 10^{16}, which rarely occurs clinically.

In adults and children with TB disease, high bacterial density assumes presence of many bacilli that are resistant to a single drug, and therapy requires two or more anti-TB drugs. A single effective drug would select for emergence of a dominantly resistant population and produce secondary drug-resistant TB. Conversely, in persons with *M. tuberculosis* infection, the low bacterial density allows the use of a single drug.

Treatment of Mycobacterium tuberculosis Infection

The number of childhood TB cases occurring in even the poorest countries can be reduced drastically with timely evaluation and treatment of child contacts of pulmonary TB patients.[208–210] Because most childhood disease occurs 2 to 9 months after infection, early intervention is highly beneficial and cost-effective.[40,211]

The decision to administer treatment should consider several aspects of the natural history of childhood TB. First, children younger than 5 years of age with TB infection were infected recently. Second, infants with untreated TB infection have up to a 40% chance of developing TB disease. Third, the risk for disease progression decreases gradually throughout childhood and then increases slightly in adolescence. Fourth, infants and young children are more likely to have life-threatening forms of TB, including meningitis and disseminated disease. Fifth, unlike adults, children with TB infection remain at risk for disease progression over many years.

Treatment of TB infection significantly reduces the risk of TB disease. Treatment options are daily or twice-weekly isoniazid for 9 months, daily rifampin for 4 or 6 months, daily isoniazid plus rifampin for 2 to 3 months, or once-weekly isoniazid and rifapentine for 12 doses (see Table 134.3).

The efficacy of isoniazid has been demonstrated by placebo-controlled trials involving more than 125,000 subjects. These studies showed a 60% median risk reduction for TB in adults after 1 year of treatment and follow-up. Among the subgroup of adults with good medication adherence, effectiveness approached 90%.[212] Because infants, children, and adolescents tolerate isoniazid better than adults and have a minimal risk of isoniazid-related hepatitis, the risk-benefit ratio for treatment of TB infection is especially favorable.[197,213] One study of 2750 children with *M. tuberculosis* infection showed a 94% reduction in TB disease during the first year after treatment and a 70% reduction over the subsequent 9-year period.[214] Other large clinical trials also demonstrated risk reductions of 70% to 90%.[215,216]

In the United States, most children receive a 9-month course of isoniazid as self-administered daily therapy or twice-weekly directly observed therapy (DOT).[141] Twice-weekly isoniazid has been used extensively to treat TB infection in children, especially school children and close contacts of cases.[217,218] Although no controlled clinical trials of intermittent treatment of childhood TB infection have been performed, an observational study of approximately 400 children younger than 18 years of age demonstrated high rates of efficacy and safety, despite the higher dose per day (see Table 134.3).[219] Although a 6-month course of treatment is recommended by the WHO to lower cost, data from large placebo-controlled trials have shown that a 9-month course confers a greater risk reduction for developing TB disease.[217]

The 4-month rifampin regimen is an alternative to isoniazid for children who cannot tolerate isoniazid or have a source case with isoniazid-resistant but rifampin-susceptible disease. Adult and pediatric studies have shown 4 months of rifampin to be *less* toxic than 9 months of isoniazid; moreover, the shorter regimen has been associated with *higher completion rates* among adults and children.[220–228] Some experts treat children younger than 12 years of age with rifampin for 6 months instead of 4 months.

A randomized, controlled trial of 1058 children between 2 and 17 years of age showed a 12-week regimen of once-weekly isoniazid and rifapentine given under DOT was as efficacious as 9 months of daily self-administered isoniazid.[229,230] No hepatotoxicity or other severe adverse treatment events were reported for children in either arm. The rifapentine group had significantly lower rates of treatment discontinuation; however, the DOT may partly explain this finding.[229]

In randomized, controlled trials of treatment of adults, 3 months of daily isoniazid plus rifampin demonstrated equivalency to 9 months of isoniazid in efficacy, adverse events, and adherence.[220,231,232] The WHO and CDC have not endorsed this regimen, but it is used in several European countries.

Guidelines do not exist for treating MDR-TB exposure or infection. A TB expert should be consulted about the management of children with either condition.[233]

No controlled studies have been published regarding the efficacy of any form of treatment of TB infection in HIV-infected children. The recommended regimen is a 9-month course of daily isoniazid.[141] Most experts recommend pyridoxine supplementation and routine monitoring of serum hepatic enzymes for HIV-infected children treated with isoniazid.

Window Prophylaxis

Isoniazid should be given to children younger than 5 years of age who have negative TST results but known or suspected exposure to a contagious source case. The rationale for this therapy—known as *window prophylaxis*—is that an untreated child may develop severe TB disease before TST reactivity develops (8–10 weeks). Children receiving window prophylaxis should have a repeat TST at 8 to 10 weeks after contact with the source case has been broken by physical separation or adequate initial treatment of the source case. If the second TST result is positive, isoniazid therapy is continued for the full 9 months, but if it is negative, treatment can be stopped.

Treatment Regimens for Tuberculosis Disease

Drug-Susceptible Pulmonary Tuberculosis

Early regimens for pulmonary TB lasted 12 to 18 months. Although they were effective, poor adherence led to high failure rates. Extensive adult and pediatric studies have shown that short-course chemotherapy—6-month regimens that typically consist of a 2-month intensive phase using 3 or 4 drugs followed by a 4-month continuation phase using 2 drugs—cures most forms of TB.[199,234–238] The efficacy of short-course chemotherapy depends on the use of multiple bactericidal drugs in the intensive phase and monitored adherence with DOT.[239]

To treat pulmonary TB, the American Academy of Pediatrics and the American Thoracic Society endorse standard RIPE therapy: 6 months of isoniazid plus rifampin supplemented during the first 2 months by pyrazinamide plus ethambutol (see Table 34.3).[240,241] Ethambutol is safe in children and helps prevent the emergence of rifampin or isoniazid resistance.[242] If the isolate from the child or the likely source case is susceptible to isoniazid and rifampin, ethambutol can be stopped. The WHO endorses decreasing the frequency of medication administration from daily to thrice-weekly at the start of the continuation phase for non-HIV–infected children in settings with strong DOT programs.[190] Although not recommended by the WHO, daily therapy for the first 2 weeks followed by twice-weekly therapy under DOT has been shown to be as safe and effective (>95% cure rate) as longer durations of daily therapy.[234,237]

Treatment regimens for pulmonary TB depend on the extent of disease, medication adherence, adverse drug reactions, and clinical and bacteriologic response. Some experts consider a 6-month regimen of only isoniazid and rifampin adequate therapy for children with hilar adenopathy, no other radiographic abnormalities, and minimal risk of drug-resistant TB. If the chest radiograph shows pulmonary cavitation or slow improvement or sputum culture remains positive after 2 months of therapy, treatment duration should be extended to 9 months.

Extrapulmonary Tuberculosis

No clinical trials comparing treatment regimens for childhood extrapulmonary TB have been conducted. Several pediatric trials of 6-month, three-drug regimens included cases of lymph node and disseminated TB; both disease types responded favorably to short-course chemotherapy.[235,243] Most treatment data for extrapulmonary TB come from case series of adult patients; according to these reports, most non–life-threatening forms respond well to the 6-month RIPE therapy used for pulmonary TB.[244,245] One exception is bone and joint TB, for which 9 to 12 months of treatment is recommended because 6-month regimens (especially without surgical intervention) have been associated with a higher failure rate.[246,247]

Similarly, most experts treat childhood TB meningitis for 9 to 12 months. For a patient with a low likelihood of drug-resistant TB, isoniazid, rifampin, and pyrazinamide constitute the first three drugs. A study from Thailand demonstrated better survival and lower morbidity when pyrazinamide was added to the initial 2 months of treatment.[248] Ethionamide, levofloxacin, amikacin, kanamycin, or streptomycin serves as the fourth drug. The fourth drug may be stopped after confirmation of susceptibility to isoniazid and rifampin. After the 2-month intensive phase, pyrazinamide may be discontinued if the patient has demonstrated good clinical response. An alternative regimen used extensively in South Africa is four drugs (i.e., isoniazid, rifampin, pyrazinamide, and ethionamide) given daily for 6 months (or 9 months for HIV-infected patients).[98,103]

Regimen recommendations for childhood TB meningitis derive from observational studies and clinician experience.[97] The only component of therapy that has been supported by randomized, controlled trials is the administration of daily corticosteroids (1 to 2 mg/kg/day of prednisone or its equivalent) during the first month of therapy.[249,250]

Special Circumstances

Treatment of Tuberculosis Infection in HIV-Infected Children.

The optimal therapy for TB in HIV-infected children has not been established; the only treatment outcome data are from small case series.[55,251,252] Children and adults with HIV-TB coinfection usually achieve cure with RIPE therapy if total treatment duration is extended to 9 months (i.e., isoniazid plus rifampin for 9 months supplemented by pyrazinamide plus ethambutol for the first 2 months) or to 6 months after sputum smears and cultures become negative, whichever is longer.[55,252,253] Intermittent, including thrice-weekly, therapy is not recommended for HIV-infected patients. Rifabutin can replace rifampin in patients receiving protease inhibitors; however, experience in children is limited.[254–256]

Infants of Mothers With Tuberculosis.

An infant whose mother or other household contact may have TB is at high risk for infection and disease. If possible, separation of the mother or contact and infant should be minimized. Recommendations for various clinical scenarios follow.[141]

Infected Household Contact With No Evidence of Disease.

Other household and extended family members to whom the infant may be exposed should undergo evaluation for TB. If no other household or family members show evidence of disease, the infant does not need further assessment. Treatment for TB infection should be considered for the contact and any other household or family members with TB infection.

Mother With Disease Who Is Noncontagious at Delivery.

Contact investigation of household and extended family members is mandatory. The neonate should have a chest radiograph and complete physical examination to evaluate for congenital TB. If the chest radiograph and examination are unremarkable, the infant should receive isoniazid. Separation of the mother and infant is unnecessary if treatment and follow-up are ensured. The infant can breastfeed safely.

The infant should have a TST at 3 to 4 months. Isoniazid can be discontinued if the TST result and physical examination are normal, the mother adheres to therapy and shows satisfactory response, and no other close contacts have infectious TB. If the infant has a positive TST result, isoniazid should be continued for the full 9-month course.

Mother With Disease Who Is Suspected to Be Contagious at Delivery.

Management is the same as for the infant of a mother who is noncontagious at delivery, with the exception that while the mother remains contagious, contact between mother and infant should be limited to short periods, during which the mother must wear a mask.

Drug-Resistant Tuberculosis

The drug susceptibility pattern of the likely source case should guide empiric therapy while the child's own DST results are pending. Most cases of childhood pulmonary TB that are isoniazid-resistant but rifampin- and pyrazinamide-susceptible can be treated with a 6-month regimen of rifampin plus pyrazinamide plus ethambutol given daily or thrice weekly. Because of its inherent pyrazinamide resistance, *M. bovis*, barring additional drug resistance, should be treated with isoniazid and rifampin for 9 months, accompanied by ethambutol for the first 2 months.

MDR-TB regimens usually involve four or more drugs to which the patient's strain is susceptible and last 12 to 24 months. The use of an injectable drug, such as amikacin, for the first 6 months has been associated with improved outcomes but also with ototoxicity.[257–259] Intermittent administration of medications is not recommended for resistant TB, and daily DOT is critical to prevent emergence of additional resistance. Several resources provide a more comprehensive overview of the management of childhood drug-resistant TB.[260–262] A TB expert should be involved in designing the treatment regimen for all drug-resistant cases.

MDR-TB treatment guidelines for children are based on adult studies.[258,263,264] Pediatric data are scarce, but clinical experience and observational reports support several generalizations. First, children tolerate second-line therapy well, despite the lack of pediatric dosages. Second, children with intrathoracic TB respond favorably when the regimen includes three or more drugs to which the isolate is susceptible. Third, children with TB meningitis, HIV infection, or poor access to health resources have worse outcomes. Fourth, outpatient therapy for most or all of the treatment course is not associated with worse outcomes.[257,260,265]

The US Food and Drug Administration has approved bedaquiline for adults with MDR-TB. No pediatric data exist for the drug's safety, tolerability, efficacy, or pharmacokinetics.[266]

Adjunctive Measures and Monitoring

Corticosteroid Therapy

Corticosteroids are beneficial in the management of childhood TB when host inflammatory response contributes significantly to tissue damage or impaired function.[267] Corticosteroids decrease mortality rates and long-term neurologic sequelae for patients with TB meningitis by reducing vasculitis, inflammation, and increased intracranial pressure.[249,250,268] Corticosteroids also are used for a CNS inflammatory mass that arises during therapy for TB meningitis; enlarged hilar lymph nodes that compress the tracheobronchial tree, causing respiratory distress, localized emphysema, collapse, or consolidation[269]; and miliary disease associated with alveolar-capillary block, pleural effusion, or pericardial effusion. The most commonly used agent is prednisone at 1 to 2 mg/kg/day for 4 to 6 weeks followed by a taper.

Follow-Up During Antituberculosis Therapy and Directly Observed Therapy

The primary goals of treatment monitoring consist of ensuring adherence, watching for adverse drug reactions, and assessing clinical response. In the United States, TB cases must be reported to the local public health department, which assists with treatment monitoring, compiles statistics, and performs necessary contact investigations. Moreover, public health officials should be promptly alerted about nonadherence and missed appointments because they may be able to help patients overcome barriers to adherence to therapy and clinic visits. The use of DOT in adult populations with increased risk factors for nonadherence (e.g., homelessness, intravenous drug use, HIV infection, lower socioeconomic status) demonstrated reductions in drug resistance, overall relapse rates, and relapses with MDR organisms.[270] Children and adolescents with TB should be managed with DOT whenever possible.[190,218]

Children have low rates of adverse reactions to anti-TB medications.[141,193] Asymptomatic mild elevations (i.e., more than three times the normal level) of serum ALT occur frequently during isoniazid or rifampin therapy, do not predict hepatotoxicity, and are not indications for discontinuing drugs. With the exception of pregnant or postpartum adolescents, who may have an elevated risk of hepatotoxicity, pediatric TB patients do not usually require routine biochemical monitoring. Rather, their caregivers should receive education regarding signs and symptoms of adverse events (e.g., anorexia, vomiting, abdominal pain, jaundice), which should prompt discontinuation of all medications and evaluation by a physician. Children taking ethambutol require regular monitoring of visual acuity and color discrimination if they can cooperate with testing.

While receiving chemotherapy, the patient should be seen periodically to encourage regular intake of the prescribed drugs and to assess treatment response and possible adverse drug effects. Because radiographic improvement of intrathoracic TB occurs slowly, routine chest radiographs typically need to be obtained only at diagnosis, 1 or 2 months into treatment, and at the conclusion of therapy. Normal chest radiograph appearance is not a necessary criterion for treatment completion. Hilar lymphadenopathy commonly persists for 2 to 3 years after therapy.

Adults and children with HIV infection and tuberculosis may develop IRIS if antiretroviral drugs are started with or shortly after the initiation of anti-TB therapy.[271,272] As the HIV load drops and the $CD4^+$ lymphocyte count rises, TB disease appears to worsen, or new foci of infection (e.g., tuberculoma of the brain, abdominal lesions) appear despite effective chemotherapy. IRIS is an immunologically mediated phenomenon and does not indicate inadequate anti-TB treatment. The addition of corticosteroids to the treatment regimen usually hastens resolution of new lesions.

Bacillus Calmette–Guérin Vaccine

Despite decades of routine use of BCG vaccines in every country except the Netherlands and the United States, TB remains a major cause of morbidity and mortality worldwide.[273] The lack of known in vitro correlates for immunity to *M. tuberculosis* poses a major obstacle to TB vaccination. However, increased understanding of TB immunity has led to efforts to produce a more effective vaccine, and several vaccine candidates are in various stages of development.[274]

Studies suggest that BCG vaccination can confer some protection against infection with *M. tuberculosis*.[275] Meta-analyses of published trials and case-control series suggest that BCG vaccination of children prevents about 50% of all cases of TB disease, 60% to 80% of severe cases (especially meningitis and miliary disease), and 60% to 80% of deaths from TB.[91,276–278] Strong evidence supports the use of BCG vaccines in TB high-burden countries to prevent meningitis and disseminated disease in young children, but in 2011, vaccination rates in high-burden countries were only 47% to 85%.[279]

In the United States, the low risk of *M. tuberculosis* infection in the general population and the vaccine's limited efficacy render universal BCG vaccination inappropriate. However, BCG vaccination is recommended for infants and children with negative TST results who have a high risk of intimate and prolonged exposure to persistently untreated or ineffectively treated people with infectious pulmonary TB, cannot be removed from the source of exposure, and cannot be given appropriate preventive therapy.

BCG vaccine is contraindicated in some patients: those whose immunologic responses are impaired because of HIV infection, congenital immunodeficiency, or generalized malignancy (e.g., leukemia, lymphoma); persons receiving corticosteroids, alkylating agents, antimetabolites, or irradiation; and pregnant women.[280] Patients who are undergoing TB treatment or who receive BCG vaccine can be given measles or other live virus vaccines unless they are taking corticosteroids, are severely ill, or have specific vaccine contraindications.

Complications of BCG vaccine include BCG lymphadenitis and abscesses. Immunosuppressed individuals and occasionally young children can develop infection at disseminated sites (e.g., bone, brain, liver, lung).[281–289] Standard anti-TB therapy is recommended to treat osteitis and disseminated disease caused by BCG and can be considered for treatment of chronic suppurative lymphadenitis when surgical excision cannot be performed.

Mycobacterium Nontuberculosis Species

Marc Tebruegge, Nigel Curtis

The growing importance of nontuberculous mycobacteria (NTM) in the past 2 decades prompted development of sophisticated microbiologic techniques that enable more rapid and accurate identification of older species and identification of species that are emerging as human pathogens.[1–3] More than 160 species of mycobacteria are currently recognized.

Epidemiology

NTM species are ubiquitous in soil, water, foodstuffs, and domestic and wild animals.[4,5] Human strains of *Mycobacterium avium* and *M. intracellulare* (collectively called *M. avium* complex [MAC]) are found in fresh and brackish waters in warm climates and in some animals, particularly swine. Bird strains of *M. avium* are molecularly different from human strains.[6] Tap water has emerged as the major reservoir for several NTM species, including *M. kansasii, M. xenopi, M. gordonae, M. simiae,* and *M. mucogenicum,*[7] *M. fortuitum, M. chelonae,* and *M. abscessus.*[4] Fish and fish tank water are a major reservoir for *M. marinum.*[8–12] Rapidly growing mycobacteria (i.e., *M. fortuitum, M. mucogenicum, M. immunogenum,* and *M. abscessus)* are associated with healthcare-associated infections, most likely from environmental sources.[13–17] When identical methods are used, isolation rates of NTM are remarkably similar in diverse geographic areas.[18]

There are particular geographic regions in which pathogenic species are found more commonly in the local environment and as etiologic agents of disease.[19] These include *M. simiae* (e.g., southwestern United States, Europe, Israel), *M. malmoense* (e.g., northern and central Europe), *M. xenopi* (e.g., Canada, United States, Europe), *M. ulcerans* (e.g., Africa, Australia), and *M. kansasii* (e.g., Europe, areas of the central and southern United States).[18–36]

The incidence of human disease due to NTM increased significantly in the 1980s and 1990s in parallel with increasing numbers of AIDS cases.[37] Epidemiologic data suggest that the incidence of infections due to NTM among immunocompetent individuals has also risen in the past few decades.[19,20,34,35,38–40] The changes in incidence may be real or may reflect increased awareness and enhanced laboratory detection.[19,35]

One study of children found seasonal variation in the incidence of NTM disease in temperate climates. Peaks occurred in late winter and spring, and troughs occurred in autumn,[41] analogous to the reported seasonality for tuberculosis.[42]

Pathogenesis

The pathogenesis of NTM infection in humans is not well understood. Humans are thought to acquire these organisms primarily from environmental sources. Although it was previously thought that there is no human-to-human transmission,[18,40,43–46] data from cases with cystic fibrosis (CF) suggest that *M. abscessus* can be transmitted between patients.[47] Pulmonary NTM infection results from inhalation of airborne organisms, whereas skin and soft tissue infections result from direct inoculation. Ingestion of NTM can result in gastrointestinal disease or cervical lymphadenitis. Although the pathogenesis of disseminated disease, especially for rapidly growing mycobacteria, is not understood completely,[48] colonization of central venous catheters (CVCs) may be important.

Many host factors that increase the risk of NTM infection have been identified.[18] Each species has a characteristic level of virulence and propensity to cause infection in particular organs or settings (Table 135.1). This includes contaminated wounds and open fractures (e.g., *M. fortuitum, M. goodii*), prosthetic devices such as indwelling CVCs (e.g., *M. fortuitum, M. mucogenicum*) and prosthetic heart valves (e.g., *M. fortuitum, M. abscessus),*[48–50] tympanostomy tubes (e.g., *M. abscessus*, MAC),[14,17] immune suppression with organ transplantation (e.g., *M. chelonae, M. abscessus*),[51] and bronchiectasis in the setting of CF (e.g., MAC, *M. abscessus*).[52–54] Another iatrogenic factor predisposing to mycobacterial disease is treatment with tumor necrosis factor-α (TNF-α)–inhibiting agents (e.g., infliximab, etanercept), usually in the context of rheumatoid arthritis or inflammatory bowel disease[55–58] (see Chapter 107).

TABLE 135.1

Clinical Manifestations of Infection Caused by Nontuberculous Mycobacteria

Site	Predominant *Mycobacterium* Species	Typical Lesions	Setting
Skin and soft tissue	*M. marinum*	Papular, nodular, or plaque-like; less commonly ulcerative	Usually associated with aquatic trauma (aquarium granuloma, swimmer's granuloma)
	M. fortuitum	Granuloma	Postoperative, central venous catheter associated, after trauma or penetrating injury
	M. abscessus	Granuloma	
	M. chelonae	Granuloma	
	M. ulcerans	Ulcer	Mode of transmission is uncertain
Lymphadenitis	*M. avium* complex	Submandibular or anterior cervical mass	Typically unilateral; subacute; 1–5 yr olds
	M. haemophilum		
	M. malmoense[a]		
Otitis media and mastoiditis	*M. abscessus*	Chronic otorrhea; unresponsive to conventional antibiotics	Almost exclusively in patients with tympanostomy tubes in situ
	M. avium complex		
Pulmonary infection	*M. avium* complex	Cavitation or nodular disease and bronchiectasis	Typically in patients with preexisting lung disease; cystic fibrosis and bronchiectasis in children and adolescents; chronic obstructive pulmonary disease in adults
	M. kansasii		
	M. abscessus		
	M. fortuitum		
	M. simiae[a]		
Disseminated infection	*M. avium* complex	Organism recovered from	Immunocompromised host (malignancy, impaired cell-mediated immunity, HIV

	M. kansasii *M. abscessus* *M. chelonae* *M. haemophilum*	blood, bone marrow, liver, and lymph nodes	infection, immunosuppressive treatment or chemotherapy)

[a] Common only in certain geographic areas.

Investigation of genetic polymorphisms that increase host susceptibility to NTM is ongoing. The interferon γ (IFNγ), TNF-α, and interleukin-12 (IL-12) pathways play an important role in the host immune response to mycobacterial infections. Isolated immune defects identified in patients with disseminated mycobacterial infections include mutations in the IFNγ receptor gene and IL-12 receptor deficiency.[59–65]

Virulence factors that enhance the invasiveness of NTM species largely are unknown, in part because comparatively few NTM species have undergone genomic sequencing. The complete genome of *M. ulcerans* was published in 2007, followed by the genomes of *M. avium, M. marinum,* and *M. abscessus*.[66–71] Additional NTM species have been sequenced since then.[72–74] *M. ulcerans* produces mycolactone, a polyketide toxin that induces tissue necrosis and has immunosuppressive properties.[75] The genes required for mycolactone production are plasmid encoded.[76]

Laboratory Diagnosis

The mycobacterial species, the site of specimen origin, and quantity of growth in culture are important factors in assessing the potential pathogenic role of an NTM isolate.[18] Heavy growth of a single organism usually indicates infection, whereas light growth in a single sputum sample may indicate colonization or contamination.[18] This does not apply to normally sterile body fluids or bronchoalveolar lavage (BAL) fluid, in which NTM isolation confirms infection.[18] Recommendations for isolation and interpretation of culture results are published.[18] Because some NTM have unusual requirements for nutrition and incubation (e.g., *M. haemophilum, M. ulcerans, M. genavense, M. marinum*),[2,9,18,77] laboratory staff should be consulted to optimize specimen collection and culture conditions.

Conventional methods used for *M. tuberculosis* remain useful for processing and staining of specimens for NTM before culture.

Typically, *N*-acetyl-L-cysteine is used as a mucolytic agent to free acid-fast bacilli from proteinaceous material, followed by 2% sodium hydroxide to kill non–acid-fast organisms. However, some NTM species, especially rapidly growing mycobacteria such as *M. abscessus*, are highly susceptible to sodium hydroxide and lose viability.[78] Chlorhexidine decontamination may be preferable when *M. abscessus* is suspected.[78] For tissue samples and fluids from normally sterile sites, decontamination procedures are not required.[18]

Fluorochrome, Kinyoun, and Ziehl-Neelsen stains are used for direct staining.[3,18] Because the appearance of mycobacteria in stained specimens varies, experience is required for accurate interpretation. Colony morphology, growth rates, and pigmentation are superior to microscopic morphology as an indication of mycobacterial group; however, neither should be used to identify species.

Standard culture methods involve a combination of broth and solid media. Although most NTM species grow well with standard incubation at 37°C, some species, including *M. ulcerans* and *M. marinum*, grow poorly or not at all at 37°C. If these organisms are suspected, additional cultures should be incubated in parallel at 30°C to 32°C.[9,79,80]

Historically, isolation on solid media required 2 to 4 weeks, and identification based on biochemical tests took another 4 to 6 weeks. However, the use of broth culture incubation systems, such as the BioFM (Bio-Rad) and the Bactec MGIT 960 (Becton Dickinson), has reduced the time for detection of growth to an average of 1 to 2 weeks, depending on species and positivity of direct smear.[3,81–83] A more rapid method for mycobacterial species identification is cell wall mycolic acid analysis by thin-layer chromatography, gas-liquid chromatography, or high-performance liquid chromatography (HPLC).[1,84–87]

Use of matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry has been explored for NTM species identification.[88,89] A variety of molecular methods also can be used for species identification, including commercial DNA probes (e.g., *M. tuberculosis* complex, MAC, *M. gordonae, M. kansasii*) (AccuProbe, Gen-Probe) and commercial hybridization strips (i.e., line probe assays) for multiple species (INNO-LiPA Mycobacteria v2, Fuji-Rebio; GenoType Mycobacterium CM/AS, Hain Lifescience; MolecuTech REBA Myco-ID, YD Diagnostics).[18,90–94] Other methods include a commercial 16S rRNA gene sequencing kit (MicroSeq, Applied Biosystems),[95,96] noncommercial (in-house) sequencing and polymerase chain reaction (PCR) plus restriction fragment length polymorphism (RFLP) analysis (PRA) of the *hsp*65 gene.[97–100]

Methods to detect and identify NTM directly from clinical specimens are being studied, including DNA probes, target amplification methods (e.g., PCR), signal amplification methods, and gene amplification.[3,101] The most effective of these has been amplification, followed by identification of the 16S rRNA or *hsp65* gene.[3,101] None of the PCR-based methods are available commercially, and both gene targets suffer from the fact that they are single-copy genes, which greatly reduces detection sensitivity.

NTM have been identified by means of pyrosequencing of the hypervariable regions of the 16S rRNA gene.[102–104] This method allows higher throughput, is usually less expensive than traditional chain-termination (Sanger) sequencing, and has a high level of accuracy for differentiating among mycobacterial species. The automated, PCR-based GeneXpert system (Cepheid) allows rapid detection of *M. tuberculosis* combined with testing for rifampicin resistance genes with the Xpert MTB/RIF assay. Although this system is useful for *M. tuberculosis* and has become widely available across North America and Europe,[105–108] it has not yet been developed to test for NTM. The Xpert MTB/RIF assay and most other PCR-based assays target genes within the MTB complex and therefore detect all eight species within the MTB complex, including *M. africanum* and *M. bovis* (including BCG).[109] Most assays, including the Xpert MTB/RIF, target the 1610 gene, which is shared also by *M. smegmatis*.[110]

Standardized procedures for susceptibility testing of NTM in broth systems have been published.[111] Susceptibility or resistance of NTM species in vitro often does not correlate well with clinical efficacy, with the exception of clarithromycin resistance for treatment of disseminated or pulmonary MAC, clarithromycin resistance for *M. chelonae* and *M. abscessus* infections, and rifampin resistance for pulmonary *M. kansasii*.[112–115]

Immunoassays for the Diagnosis of

Nontuberculous Mycobacterial Infections

IFNγ release assays (IGRAs) have emerged as a tool for the diagnosis of tuberculosis.[116,117] Both available commercial assays, the QuantiFERON-TB Gold in-Tube (QFT-GIT) assay (Cellestis/Qiagen) and the T-SPOT.*TB* assay (Oxford Immunotec), incorporate early secretory antigenic target 6 (ESAT-6) and culture filtrate protein 10 (CFP-10) as stimulatory antigens, which are absent from most NTM, with the notable exceptions of *M. kansasii*, *M. marinum,* and *M. szulgai*.[116–118] IGRAs overall have greater specificity for tuberculous infections compared with the Mantoux tuberculin skin test (TST).[119] However, IGRAs have several limitations, particularly in children: (1) less robust performance in young children,[120–124] (2) high proportions of indeterminate (i.e., uninterpretable) results in some pediatric studies,[120,123,125,126] and (3) incomplete understanding of the mechanisms underlying discordance with TST results, which is frequently attributed (without definitive evidence) to prior BCG vaccination or exposure to NTM.[120,127–130]

In one study of children with mycobacterial lymphadenitis (mainly caused by *M. avium*), the QuantiFERON-TB Gold assay and the T-SPOT.TB assay showed a greater ability to discriminate between tuberculous and NTM lymphadenitis than the tuberculin skin test (TST).[131] Other reports support their usefulness to differentiate pulmonary infections due to MTB from certain NTM infections, including MAC, *M. malmoense*, *M. genavense,* and *M. gordonae*.[132–137] A negative IGRA result does not exclude MTB.[138] The pooled sensitivity of the QFT-GIT assay and T-SPOT.*TB* assay for patients with active tuberculosis in a meta-analysis was only 81% and 88%, respectively.[139] A positive IGRA result does not prove *M. tuberculosis* infection because most patients with NTM disease caused by *M. kansasii*, *M. marinum,* or *M. szulgai* have positive IGRA results.[133,134,137,140,141] Case reports suggest that IGRAs can be useful to support a suspected diagnosis of *M. marinum* skin infection when PCR and culture results are pending.[142,143]

Clinical Manifestations

Localized Skin, Soft Tissue, and Bone

Infections

The NTM responsible for most posttraumatic or postsurgical skin and soft tissue infections are *M. marinum, M. ulcerans, M. fortuitum, M. chelonae,* and *M. goodii.*[18,48,144–147] Diagnosis requires demonstration of the organism in a biopsy specimen or culture of aspirated fluid from a skin nodule, wound, or abscess. In immunocompetent hosts, cutaneous NTM infection usually represents the primary site of infection after local trauma.[48] In immunocompromised hosts, cutaneous lesions can be a manifestation of disseminated disease.[18,148–150]

Infection with *M. marinum* usually follows cutaneous trauma in nonchlorinated swimming pools, aquariums, or natural bodies of water,[8,9,142,151,152] most commonly after exposure in home aquariums.[8,9,12] *M. marinum* infection also can follow injuries inflicted by marine life (i.e., fish spines or bite injuries). Lesions may be singular but typically are clusters of nontender papules or nodules; erythematous plaques have also been reported. Lesions usually occur on the elbows, legs, and feet in pool-related cases and on the hands and arms of aquarium owners; truncal lesions are rare. A sporotrichoid distribution (i.e., linear distribution along lymphatic vessels) of multiple lesions is seen in about one fourth to one third of cases.[12,153–155]

Regional lymphadenitis or systemic symptoms are rare.[12] Locally invasive disease, including tenosynovitis, arthritis, and osteomyelitis, is uncommon.[156] Disseminated infection is rare and occurs almost exclusively in immunocompromised hosts.[8,150,157,158]

M. ulcerans infection mainly occurs in sub-Saharan Africa and Australia, where it is referred to as Buruli ulcer or Bairnsdale ulcer, respectively.[18,24,25,29,144,159–162] Cases also are reported from some Asian countries and Latin America.[159,160,163–167] The infection is most commonly acquired in riverine and coastal areas, and aquatic insects or mosquitos may play a role.[160,168,169] The initial lesion is a single, subcutaneous nodule, which evolves into a painless, undermined ulcer that is typically located on the extensor surface of the lower extremities. Local necrosis and occasionally widespread secondary necrosis occur with or without satellite lesions. The infection can spread to deep tissue planes. Healing proceeds slowly over 6 to 9 months, often resulting in severe limb deformity.[161]

Lymph node enlargement and systemic symptoms are rare.

M. fortuitum, M. abscessus, and *M. chelonae* are rapidly growing mycobacteria that cause a spectrum of cutaneous infections.[48] Primary cutaneous disease often follows penetrating injury and usually manifests as localized cellulitis, a draining abscess, or an individual nodule with minimal tenderness.[18,36,48,145,151] Outbreaks of cutaneous abscesses after injections have been associated with use of contaminated multiple-dose vials.[15,16] Outbreaks of postoperative wound infections have been reported after median sternotomy,[48,170,171] plastic surgery using contaminated gentian violet,[172] and plastic surgery procedures such as liposuction and mammaplasty.[13,48] Sporadic infections have been associated with a wide variety of surgical procedures. Unlike other bacterial infections, there often is a considerable gap between the surgical procedure and the onset of symptoms (1–5 weeks).[170] Patients have poor wound healing or breakdown of a healed wound, with drainage of serous fluid. *M. fortuitum* has been associated with infections of the foot after puncture wound, which can be indistinguishable clinically from pseudomonal or staphylococcal infection.[36,48,147] The most common healthcare-associated NTM infection is CVC infection due to *M. fortuitum*.[18,49,50]

MAC can cause synovial infection, usually manifesting as tenosynovitis of the hands or upper extremity. Infection usually is localized and results from local trauma. Skin lesions due to MAC are rare and usually are a manifestation of disseminated disease (Fig. 135.1).[149]

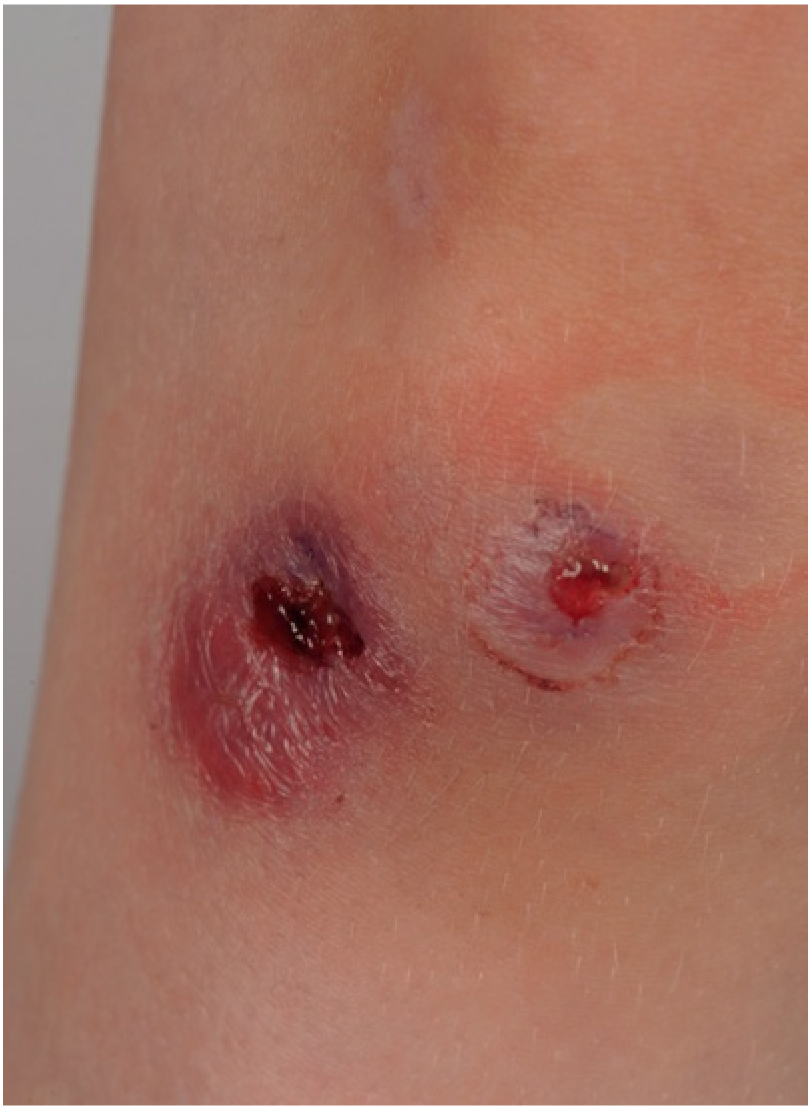

FIGURE 135.1 The lesion on the right knee of a previously well 5-year-old girl developed over a 1- to 2-month period and did not respond to conventional antibiotics. Biopsy of the lesion showed granulomatous inflammation and acid-fast bacilli. *Mycobacterium avium* complex (MAC) was identified by culture. Skin infection due to MAC is rare and occurs almost exclusively in immunocompromised hosts, but in this case, immunologic investigations, including testing of the IFNγ/IL-12 pathway, did not reveal evidence of immunodeficiency. The lesion resolved almost completely within 3 months of starting a combination of rifampin and clarithromycin.

Infection of bones, bursa, and tendon sheaths can follow penetrating trauma or surgical procedures. The most common causative agent in these situations is *M. fortuitum.* Less commonly, *M. terrae* complex, MAC, and *M. goodii* are implicated.[18] Rare cases of osteomyelitis in children have been reported. The clinical presentation of skeletal NTM infection (especially vertebral osteomyelitis) resembles that of tuberculosis and has an indolent, chronic course.[173]

Lymphadenitis

Lymphadenitis is the most common manifestation of NTM infection in children, usually occurring in otherwise healthy children younger than 12 years of age (peak incidence, 1–5 years).[18,20,36,38,41,151,173–179] Children older than 12 years with mycobacterial adenitis usually have MTB infection.[175,178] In industrialized nations with a low prevalence of tuberculosis, NTM infections account for most cases of chronic cervical or submandibular lymphadenitis.[176] MAC accounts for 70% to 90% of cases of culture-positive NTM lymphadenitis, although *M. scrofulaceum* (now rare) was the predominant etiologic agent when the disease was first recognized.[18,20,21,36,38,41,151,173–180]

In northern and central Europe, a significant proportion of NTM lymphadenitis is caused by *M. malmoense*.[20,180] The importance of *M. haemophilum* as a cause of cervical lymphadenitis was previously underestimated because of its unusual growth requirements (i.e., iron supplementation and optimal incubation temperature of 30°C).[77,179,181,182] The proportion of *M. haemophilum* in some series approaches 25%.[176] Other uncommon causative agents are *M. kansasii, M. simiae, M. chelonae,* and *M. fortuitum.* [21,22,36,174,176–178,183]

Lymphadenitis due to NTM usually is unilateral and most commonly involves the anterior cervical or submandibular lymph nodes (Fig. 135.2); the preauricular lymph nodes are affected less often.[38,174–177,179,180,183,184] In about 5% of patients, lymphadenitis involves intrathoracic (paratracheal or mediastinal) nodes.[175,185]

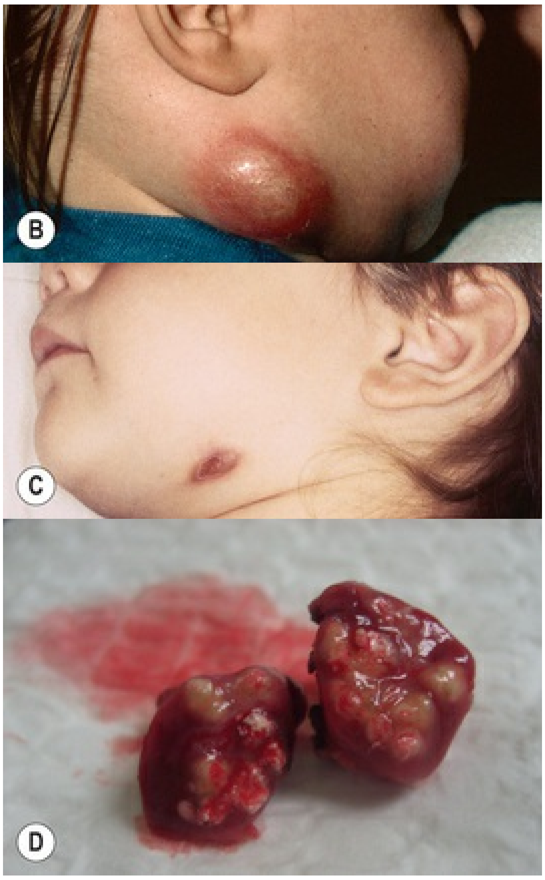

FIGURE 135.2 Three toddlers with characteristic ages, sites, appearances, and courses of nontuberculous lymphadenitis. (A) The patient had a 9-mm reactive tuberculin skin test result and was treated with clarithromycin. The node regressed without suppuration. (B) The patient had typical erythematous, effaced skin overlying an abscess caused by *Mycobacterium avium* complex. Management included aspiration, antimycobacterial therapy, and surgical excision. (C) Photograph of the patient was taken 7 months after incision and drainage were performed because of misdiagnosis of acute lymphadenitis and 6 months after starting clarithromycin and rifampin therapy. Eventually, intermittent drainage ceased, and the scar lightened. (D) Nine years after treatment of the patient (C), a mass recurred at the edge of the surgical scar. Two noncaseating granulomas measuring 0.7 and 1 cm in diameter were excised and confirmed by histology. (Courtesy of S.S. Long, MD, and B. Burkey, MD.)

Patients usually are well, without constitutional signs or symptoms, and have no or only mild local tenderness.[180] The lesion can be fluctuant or nonfluctuant on palpation.[175–177] If left untreated, the overlying skin often becomes violaceous and effaced as the lymph nodes enlarge and soften.[176,186] Nodes can then rupture and drain through a sinus tract to the skin for a prolonged period (see Fig. 135.2C). Infection sometimes resolves spontaneously, or lymph nodes do not rupture but heal, leading to fibrosis and calcification that can be disfiguring.[175,187] Remote recrudescence also can occur (see Fig. 135.2D).

The complete blood cell count usually is unremarkable; only a small proportion of patients have leukocytosis.[41,175,176,180] The erythrocyte sedimentation rate may be elevated.[41,175,176,180] Chest radiography is unremarkable in approximately 90% to 95% of cases.[174,175,180] Some studies reported a negative TST result for most patients[38,180]; two others found that approximately one half of cases had an induration of ≥6 mm or ≥10 mm, respectively.[177,178] Skin testing with mycobacterial sensitins (i.e., purified proteins) derived from NTM (e.g., *M. avium, M. scrofulaceum, M. kansasii*) was more sensitive than with the TST.[188] However, sensitins are currently not available for clinical use, and even in experimental settings, their usefulness is restricted by their limited ability to differentiate between TB and NTM infections.[128]

The differential diagnosis for NTM lymphadenitis is extensive and includes infection with *M. tuberculosis, Bartonella henselae,* Epstein-Barr virus, or *Toxoplasma gondii;* malignancy; and cystic hygroma (see Chapter 17). The diagnosis of NTM lymphadenitis is supported by the histopathologic appearance of the lymph node showing caseating or noncaseating granulomas.[151,175,180,182] Acid-fast bacilli are detected in approximately one half to two thirds of cases.[174,175,180] Although the TST result frequently is reactive, a negative result does not exclude NTM infection. A definitive diagnosis of NTM lymphadenitis is made by isolating NTM from a lymph node or by molecular detection. In most series (using older, conventional culture media), organisms were isolated from only about 50% of infected lymph nodes.[174,175] Later data suggest that PCR-based detection in nodal specimens has a higher sensitivity than isolation in mycobacterial culture media.[41]

Bilateral lymphadenitis and involvement of posterior cervical, supraclavicular, axillary, and inguinal nodes are features more frequently associated with tuberculosis than with NTM infections (see Fig. 134.6 in Chapter 134). Lymph nodes in cases of acute bacterial lymphadenitis often are larger, evolve more rapidly, and are more tender and erythematous. Fever is a prominent symptom, and the white blood cell count and C-reactive protein level typically are elevated.[175,187–189]

Pulmonary Infection

Previously thought to be rare in children,[5,145] NTM lung infections are recognized increasingly in the setting of bronchiectasis and especially in patients with CF.[52–54,190–192] NTM lung infection in patients with CF typically occurs in adolescents or young adults with relatively mild disease. Some infections are difficult to distinguish from the symptoms of CF, whereas other patients have fever, weight loss, and fatigue that do not respond to antipseudomonal therapy.[192] The disease appears to be more common in the south and southeastern United States, where up to 20% of adolescent CF patients are infected. The most common reported species affecting the lung in CF patients are MAC, *M. abscessus, M. chelonae, and M. fortuitum.*[53,192–194] NTM organisms should be considered as possible pathogens when recovered repeatedly from the sputum of patients with CF who have severe lung disease or pulmonary exacerbations unresponsive to broad-spectrum antibiotics.[187,191,192]

Most children with non–CF-associated, isolated pulmonary infection due to NTM are immunocompetent and have no underlying pulmonary disease.[173,195] Reported pediatric cases have been caused by MAC, *M. kansasii, M. abscessus, M. chelonae,* or *M. fortuitum.*[36,41,195–199] Signs and symptoms vary and are nonspecific, including fever, cough, dyspnea, hemoptysis, malaise, and fatigue. Weight loss and night sweats are uncommon.[27,197] Enlargement of mediastinal and hilar lymph nodes is common.[195,197] Endobronchial obstruction due to external compression or endobronchial granulation tissue can manifest as reduced air entry and persistent wheezing, mimicking foreign body aspiration.[195,197]

The diagnosis of pulmonary NTM infection should be considered for any child who has a pulmonary illness that is consistent with tuberculosis but is not responding well to usual antituberculous medications. NTM infections are increasingly recognized as a cause of graft dysfunction in lung transplant recipients.[200]

Physical examination and routine laboratory tests seldom provide etiologic clues. Chest radiographic findings are nonspecific and cannot be differentiated easily from those of tuberculosis or fungal infection. However, cavitating lesions are less common in pulmonary NTM disease compared with tuberculosis.[27] Involvement of multiple pulmonary segments is common.[201] Chest computed tomography, including high-resolution studies, is used increasingly for diagnosis and follow-up.[202] Imaging features depend on whether lung disease is primarily fibrocavitary (similar to tuberculosis) or is characterized by nodules and bronchiectasis.[18,201,202]

Isolation of NTM is essential for diagnosis. The interpretation of a positive sputum or gastric aspirate culture is confounded by the ubiquity of NTM in the environment. A single positive culture result does not establish the diagnosis of NTM disease.[18] Diagnosis requires growth of the same NTM organism from multiple sputum samples or a BAL specimen after the exclusion of other causes for the clinical symptoms. Certain NTM that are usually nonpathogenic, including *M. gordonae*, *M. terrae* complex, and *M. mucogenicum,* are more likely to be contaminants if isolated from respiratory specimens.[18]

The American Thoracic Society (ATS) has established diagnostic criteria for NTM pulmonary infection in adults, but their validity for children has not been established.[18] The role and importance of BAL cultures in diagnosing CF have not been established, nor have the sensitivity and specificity of sputum cultures compared with BAL cultures been confirmed. When the underlying cause remains uncertain, lung biopsy should be considered to exclude other causes, to demonstrate histopathologic changes consistent with mycobacterial disease (e.g., granulomatous inflammation with or without acid-fast bacilli), and to obtain specimens for culture.[18]

Otitis Media

Otitis media with or without mastoiditis due to NTM occurs almost exclusively in children with tympanostomy tubes.[203–211] Outbreaks[17] and sporadic[14] disease have been described. The most commonly implicated NTM are *M. abscessus*, although cases caused by MAC also have been reported. Patients usually have persistent drainage unresponsive to standard antibiotic therapy.

Disseminated Infection

Disseminated disease due to NTM is rare in healthy people but can occur in immunocompromised hosts, such as patients with underlying malignancy or congenital or acquired defects of cell-mediated immunity,[8,18,48,51,150,157,158,212] patients with isolated defects in the IFNγ/IL-12 pathway,[41,63,65] solid organ and stem cell transplant recipients,[212–218] and patients on long-term corticosteroid therapy or cytotoxic chemotherapy.[212,219] These patients often exhibit skin lesions as the earliest manifestation of disseminated disease, but lesions sometimes are related to an indwelling CVC. The most common pathogens in these settings are *M. chelonae* and *M. abscessus*.[48,219] Other pathogens include MAC, *M. haemophilum*, *M. kansasii, M. fortuitum, and M. simiae*.[18,48,212,216,220]

Skin or soft tissue manifestations of *M. kansasii* infection are rare compared with rapidly growing mycobacteria and include verrucous or granulomatous papules, cellulitis, sporotrichoid eruptions, ulcers, and necrotic papulopustules.[148,212] Multiple skin nodules occurring in clusters or without a definite pattern can be associated with *M. haemophilum* infection, usually in an immunocompromised host.[18]

Disseminated disease with NTM (primarily MAC) has long been recognized in patients with AIDS and in patients with congential immunodeficiencies, including severe combined immunodeficiency (SCID).[20,221–223] MAC infection occurs in 6% to 14% of children infected with human immunodeficiency virus (HIV), with the incidence increasing to 24% among those with severe depletion of CD4$^+$ T lymphocytes (<100 cells/mm^3).[224–226] As in the adult population,[37] disseminated MAC infection usually occurs late in the course of symptomatic HIV infection in children.

Disseminated MAC infection in children with AIDS is associated with systemic symptoms, including fever, weight loss, night sweats, and gastrointestinal complaints, which often are accompanied by neutropenia or anemia, or both. Although the mortality directly attributable to disseminated MAC infection is difficult to establish, morbidity can be significant.[225,226] Early autopsy studies suggested that MAC infection is rarely a cause of death; later studies have found disseminated MAC infection to be associated with shortened survival.[37]

Clinicians should have a high index of suspicion for disseminated MAC infection in HIV-infected children with low CD4$^+$ T lymphocyte counts. Definitive diagnosis rests on recovery of MAC from blood, bone marrow, liver, visceral lymph nodes, or other normally sterile body sites.[221] MAC bacteremia can be intermittent and low grade; multiple blood specimens must be collected to detect infection.[226] A positive stool culture result can occur in the absence of symptoms and most likely represents gastrointestinal colonization or localized disease.

Immune reconstitution inflammatory syndrome (IRIS) related to NTM infection has been repeatedly described in HIV-infected patients with a good response (i.e., increasing CD4$^+$ lymphocyte counts) to antiretroviral therapy.[227–230] IRIS manifests typically as localized disease that becomes apparent as peripheral lymphadenitis, pulmonary disease, or abdominal disease. Morbidity and mortality rates for HIV-infected children with IRIS related to mycobacterial infections are high.[231] The role of corticosteroid therapy in this context has not been established firmly.[227,231]

Treatment

Many NTM species are resistant to traditional or first-line drugs used to treat *M. tuberculosis.* Antimicrobial susceptibility testing is essential for appropriate selection of an effective treatment regimen.

Localized Skin, Soft Tissue, and Bone Infections

The optimal treatment for *M. marinum* infection remains uncertain due to the absence of controlled trials. The latest ATS and Infectious Diseases Society of America (IDSA) guidelines recommend combination therapy comprising clarithromycin plus ethambutol or rifampin (international nonproprietary name is rifampicin).[18] However, the largest published study on *M. marinum* infections reported that 18% of the patients receiving clarithromycin (alone or in combination with other antimycobacterial antibiotics) failed to respond or relapsed.[12] Some experts suggest adding rifampin as a third agent in patients with bone or joint involvement.[8,9,18,232] Cases with extensive locally invasive disease may require surgical debridement. Antibiotic treatment should be continued for 1 to 2 months after resolution of all lesions.[8,9,232,233]

Traditionally, lesions due to *M. ulcerans* were universally treated by surgical excision with or without skin grafting.[159] Circumstantial evidence suggests that radical excision with a wide safety margin is more effective than more limited surgery.[234] However, incomplete cure and recurrence are not uncommon with surgery alone, even with radical excision.[161,234–236] Systemic therapy with trimethoprim-sulfamethoxazole, minocycline, dapsone, or clofazimine has been used, but clinical response in longstanding ulcerative lesions often is poor.[25,159,160,237] However, antibiotic treatment may limit the need for surgical management. Anecdotal reports and data from observational studies suggest that treatment with rifampin-containing combination therapy can be curative without surgery.[238,239] Data from a randomized, controlled trial of treatment of patients with early, limited *M. ulcerans* infection also suggest that these cases can be effectively managed with antimycobacterial treatment alone.[240] Patients in this study received rifampin plus streptomycin for 8 weeks or the same combination for 4 weeks, followed by 4 weeks of rifampin plus clarithromycin; cure rates were greater than 90% in both groups. In a pilot study that included 15 patients, an 8-week course of oral rifampin plus clarithromycin was curative without surgery.[241]

Primary cutaneous lesions due to *M. fortuitum, M. chelonae,* and *M. abscessus* require drainage of localized abscesses and removal of any foreign bodies.[18] With available antimicrobial agents, surgical excision of infected tissue is not required routinely. Because of different drug susceptibilities between and within species, susceptibility testing is essential.[18,111] *M. fortuitum* isolates usually are susceptible to several oral antibiotics, including clarithromycin, doxycycline, minocycline, sulfonamides, and fluoroquinolones.[18] However, all isolates of *M. fortuitum* contain an inducible *erm* gene that confers resistance to macrolides[242]; macrolides should therefore be used with caution.[18]

Limited data suggest that clarithromycin monotherapy is usually effective for *M. chelonae* skin infections.[18,219] Serious skin and soft tissue infections with *M. abscessus* should be treated empirically with a macrolide (i.e., clarithromycin or azithromycin) plus a parenteral agent (i.e., amikacin, cefoxitin, or imipenem).[18] The duration of therapy must be individualized according to host factors, clinical response to treatment, and extent of infection. However, the standard recommended duration of therapy for severe disease, including osteomyelitis, is 6 months.[18]

Lymphadenitis

Surgical excision with removal of all visibly affected lymph nodes has been considered to be the standard therapy for NTM lymphadenitis.[18,145,174,187,189] However, only one randomized, controlled trial investigated the efficacy of surgery compared with antimycobacterial antibiotics in children.[179] The cure rate was significantly higher for the group allocated to surgery (96%) than for the group receiving conservative treatment with clarithromycin and rifabutin (66%). However, 6 patients (12%) in the surgery group developed postoperative wound infections, and 7 (14%) had facial nerve dysfunction postoperatively, which was permanent in 1 patient (2%). Adverse events in the antibiotic group were mild and transient. Importantly, outcome is dependent on surgical expertise, and these data can therefore not be generalized. Further limitations of the study are discussed elsewhere.[41,183]

Subsequently, published data from the same study suggested that the aesthetic outcome might be better with primary surgery than with antimycobacterial treatment.[186] When complete excision is not possible, as in the case of lymphadenitis with extensive facial nerve involvement, partial excision, thorough curettage, or conservative treatment with antimycobacterial antibiotics alone are options. Because MAC is by far the most common causative agent of NTM lymphadenitis, empiric treatment with clarithromycin plus rifabutin with or without ethambutol is a suitable choice.[18,179,189,243–246] Watchful waiting (i.e., no intervention) is another option because NTM lymphadenitis is usually self-limiting.[183,247,248] However, spontaneous resolution often takes 9 to 12 months, and the child and the parents must be prepared to tolerate the physical appearance during that period.

Incisional drainage is not advisable because many patients develop a draining sinus tract as a result, and disease often recurs (see Fig. 135.2C).[174,175,184] Drainage by needle aspiration remains controversial, and sinus tract formation occurs more than infrequently with this approach.[180,183]

Pulmonary Infection

Treatment regimens for NTM pulmonary disease in children are not well established. Patients with minimal symptoms can be observed without treatment, although recognition of the pathogenicity of NTM makes this approach increasingly uncertain.

Patients with more severe clinical symptoms, radiographic findings, or persistently positive culture results require treatment.[18] The ATS/IDSA guidelines suggest using a three-drug regimen comprising clarithromycin or azithromycin, ethambutol, and rifampin or rifabutin for adults with MAC lung disease, with the addition of an intravenous aminoglycoside for severe disease.[18] The same guidelines recommend a combination of rifampin, isoniazid, and ethambutol for pulmonary *M. kansasii* infection. A study of adults with *M. kansasii* lung disease showed a regimen of clarithromycin, rifampin, and ethambutol to be effective.[249]

For adults, the guidelines recommend a duration of therapy for MAC or *M. kansasii* disease of 12 months after the sputum culture result is negative.[18] Some adults with disease confined to one lobe of the lung have benefited from surgical lobectomy, particularly if response to medical therapy was poor.[18] However, there are no uniform criteria for the selection of patients with NTM lung disease for surgical therapy.[18]

Doses, drugs, and end points of therapy have not been established for CF patients with MAC or *M. abscessus. M. abscessus* lung disease in the setting of CF usually is treatable but incurable. Long-term intravenous therapy with amikacin combined with cefoxitin or imipenem is suggested in the ATS/IDSA guidelines.[18]

The clinical and microbiologic responses of *M. abscessus* lung disease to clarithromycin have been poor despite susceptibility in vitro.[18] The *M. abscessus* species recently was divided into three new subspecies based on *rpoB* gene sequences: *M. abscessus* subsp. *abscessus [sensu stricto], M. abscessus* subsp. *massiliense,* and *M.*

abscessus subsp. *bolletii*.[250,251] Response to treatment appears to depend on the subspecies, with patients with *M. massiliense* responding better than those with *M. abscessus sensu stricto* pulmonary disease.[252] In one clinical study, inducible resistance to clarithromycin was found in all *M. abscessus sensu stricto* isolates but was not found in any *M. massiliense* isolate.[252]

Published data on newer antibiotics, including linezolid and tigecycline, for the treatment of *M. abscessus* are limited.[253–255] Adolescents with CF who are being considered for macrolide monotherapy or immunotherapy for CF should have sputum cultures for NTM before therapy and periodically thereafter. Those with repeated isolation of NTM should not receive macrolide monotherapy.[18]

Disseminated Infection

Empiric treatment of disseminated NTM infection in patients with AIDS involves a multidrug regimen comprising at least two agents: clarithromycin or azithromycin plus ethambutol. A third drug, such as rifabutin or amikacin, often is added.[18] In vitro drug susceptibilities to drugs other than the macrolides do not predict clinical outcome and should not be used to direct drug therapy.[18,111] Symptomatic improvement may take 2 or 3 weeks to 2 months, and repeated blood cultures are useful to assess reduction of the bacterial load. Neither a durable response nor an extension of survival in the absence of immune reconstitution has been demonstrated definitively in prospective clinical trials. However, when clinical improvement is observed, therapy should be continued for the lifetime of the patient or until sufficient immune reconstitution has occurred.

For patients with CVC-related infection or infection related to prosthetic devices (e.g., ventriculoperitoneal shunts, peritoneal dialysis catheters), removal of the device is essential. Choice of agents for and duration of antimicrobial therapy are based on causative species, results of in vitro susceptibility tests, and the degree of immunocompromise. It is not unusual for new skin lesions to appear during successful therapy of disseminated disease; they may be immunologically mediated. After 4 to 6 weeks of therapy for *M. chelonae*, culture of a biopsy specimen from a newly appearing lesion is expected to be sterile.[219] Treatment for *M. abscessus* infection often requires 3 to 4 months to achieve culture negativity.

In children with cancer, *M. chelonae* and *M. fortuitum* have caused infections related to venous or implanted catheters for which blood culture results were transiently positive and disseminated skin lesions persisted despite removal of the device and therapy. Treatment of bone infections, especially with open fractures and foreign material, often requires surgical debridement and prolonged multidrug therapy.[18]

Prophylaxis against disseminated MAC in adults with AIDS has been studied extensively in trials. Clarithromycin or azithromycin prophylaxis is recommended by the US Public Health Service for HIV-infected adults and adolescents whose CD4$^+$ T lymphocyte counts are less than 50 cells/mm.[3,256] Before the initiation of prophylaxis, patients must be evaluated to exclude active disease due to disseminated MAC, *M. tuberculosis,* or other mycobacterial species. Robust data do not exist for children, but prophylaxis consisting of daily clarithromycin (15 mg/kg/day divided into two doses, maximum of 500 mg/day) or once-weekly azithromycin (20 mg/kg, maximum of 1200 mg) is recommended in the US guidelines for HIV-infected children with profound CD4$^+$ lymphocytopenia.[257,258]

Nocardia Species

Ellen Gould Chadwick, Richard B. Thomson Jr.

Since the first reported case of human nocardiosis in 1890, *Nocardia* spp. increasingly have been recognized as serious human pathogens. Molecular analysis identified 80 species in the *Nocardia* genus, with ongoing evolution in the understanding of *Nocardia* taxonomy.[1,2] Although challenging, identification of *Nocardia* isolates to the species level is important to determine pathogenicity and predict antimicrobial susceptibility.[1]

The more common clinical isolates reported by laboratories in past decades as *Nocardia asteroides* have been divided into six groups based on unique antimicrobial susceptibility patterns. Initially referred to as *N. asteroides* complex groups I to VI, all six groups are valid taxonomic clusters by gene sequencing and are given species or complex names. Although not a recognized taxonomic designation, *N. asteroides* complex is used for convenience to refer to all six groups. The term *complex*, when used with one of the six species groups, refers to a cluster of multiple but similar strains that have not been studied adequately to name all as individual species (Table 136.1).

TABLE 136.1

Changing Classification of Medically Relevant *Nocardia* Species

Current Classification	Classification Circa 1990–2000	Classification Before 1990
***Nocardia abscessus* complex**[a]	*Nocardia asteroides* complex group I	*Nocardia asteroides*
Nocardia brevicatena-paucivorans	*Nocardia asteroides* complex	*Nocardia asteroides*

complex[a]	group II	
***Nocardia nova* complex**[a]	*Nocardia nova* (group III)	*Nocardia asteroides*
***Nocardia transvalensis* complex**[a,b]	*Nocardia asteroides* complex group IV	*Nocardia asteroides*
Nocardia farcinica	*Nocardia farcinica* (group V)	*Nocardia asteroides*
Nocardia cyriacigeorgica	*Nocardia asteroides* complex group VI	*Nocardia asteroides*
***Nocardia otitidiscaviarum* complex**[a]	*Nocardia otitidiscaviarum*	*Nocardia caviae*
Nocardia brasiliensis	*Nocardia brasiliensis*	*Nocardia brasiliensis*
Nocardia pseudobrasiliensis	*Nocardia pseudobrasiliensis*	*Nocardia brasiliensis*

[a] These taxa include diverse strains within the species groups. It is recommended that the term *complex* be used with the species names to indicate their heterogeneity and that the taxonomy eventually be more clearly defined.[2]

[b] *N. wallacei* is the most common species encountered in the *N. transvalensis* complex and is frequently referred to by *N. wallacei* rather than *N. transvalensis* complex.

Data from References 1, 2, 43, 64.

Current designations for the *N. asteroides* complex are *N. abscessus* complex, *N. brevicatena-N. paucivorans* complex, *N. nova* complex, *N. transvalensis* complex, *N. farcinica,* and *N. cyriacigeorgica.*[2–4] The *N. farcinica* and *N. cyriacigeorgica* groups each contain closely related strains that represent a single species. Using the new taxonomy, most clinically significant isolates are *N. cyriacigeorgica, N. farcinica, N. abscessus* complex, or *N. nova* complex.[2,5] Human non–*N. asteroids* complex pathogens usually are *N. brasiliensis* or *N. otitidiscaviarum* complex (formerly *N. caviae*). *N. brasiliensis* has been subdivided into *N. brasiliensis* and *N. pseudobrasiliensis.* Whereas *N. brasiliensis* infections often are limited to skin and subcutaneous tissue in healthy individuals, all species have been reported in pulmonary and systemic infections.[3,6–10]

Microbiology

The family Nocardiaceae is composed of aerobic actinomycetes and characterized by filamentous growth with true branching. *Nocardia* spp. are catalase- and urease-positive organisms that grow on multiple media, including Sabouraud dextrose agar, Löwenstein–Jensen medium, brain-heart infusion agar, and simple blood agar. Although growth occurs over a wide temperature range, human pathogenic *Nocardia* spp. grow best at 37°C in the presence of 10% carbon dioxide. Unlike most other *Nocardia* spp., *N. farcinica* grows as well at 45°C as it does at 35°C, and this property can be used to differentiate this species.[11]

Many selective (i.e., inhibitory) media used for isolation of pathogenic fungi do not support the growth of *Nocardia* spp. Colonies can appear within 48 hours when present in pure culture; in mixed culture from clinical specimens such as sputum, other organisms often obscure small *Nocardia* colonies, making it difficult to recognize the typical morphologic characteristics before 2 to 4 weeks of incubation. Laboratory personnel should be notified to observe cultures for 4 weeks when nocardiosis is being considered. Colonies can be smooth and moist or waxy; with further incubation, development of aerial hyphae causes a velvety or chalky appearance. Primary isolates usually are light orange, but the color can vary from cream to brick red.

Microscopically, *Nocardia* spp. often are detected first on Gram stain, and they appear as delicately branched, weakly gram-positive organisms that tend to fragment into coccoid and bacillary elements (Fig. 136.1). Filaments show true branching, with irregular staining that creates a beaded appearance. Many *Nocardia* spp. are acid fast but retain fuchsin less avidly than *Mycobacterium* spp. Organisms from initial isolation are most reliably acid fast but become progressively less so on repeated subculture. A modified Ziehl-Neelsen or Kinyoun stain with the use of 1% sulfuric acid instead of acid alcohol for decoloration optimizes demonstration of acid-fast *Nocardia* in clinical specimens (Fig. 136.2).

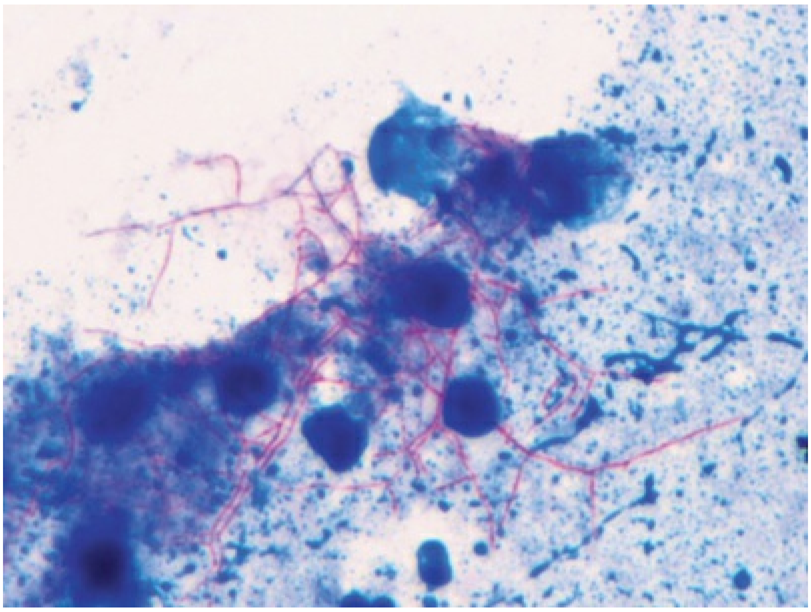

FIGURE 136.1 Gram-stained smear (oil immersion objective, ×1000) of *Nocardia* sp. in purulent sputum specimen. Notice the filamentous, branching, beaded, or stippled gram-positive rods.

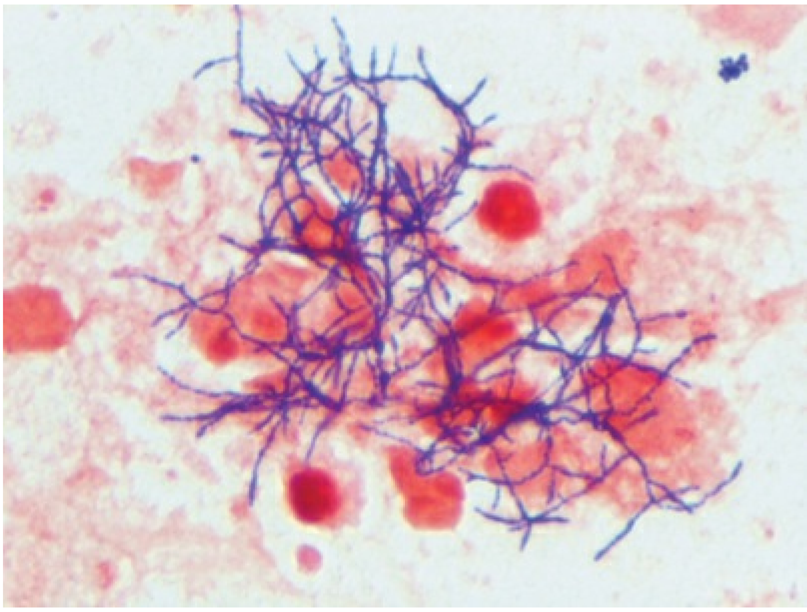

FIGURE 136.2 Modified acid-fast–stained smear (oil immersion objective, ×1000) of *Nocardia* sp. in the same purulent sputum specimen shown in Fig. 136.1.

Epidemiology

Nocardia are ubiquitous, saprophytic soil organisms that are easily aerosolized and found in house dust, garden soil, decaying vegetation, beach sand, fresh and salt water, and swimming pools. The lung is the primary portal of entry, and underlying pulmonary dysfunction with decreased bronchociliary clearance mechanisms (e.g., cystic fibrosis, asthma, bronchiectasis) predisposes to sporadic colonization, although infection rarely occurs in the absence of immunosuppression in patients with such dysfunction.[5,12,13]

Pathogenesis

Inhalation of *Nocardia* spp. can lead to primary pulmonary disease that resolves spontaneously or progresses to pneumonia.

Disseminated infection occurs by hematogenous spread from the respiratory tract, especially in immunocompromised hosts. Primary cutaneous infections usually are the result of trauma with soil contamination of the wound, resulting in infection localized to the skin and subcutaneous tissue. Keratitis that is posttraumatic or associated with contact lens use and endophthalmitis have been reported.[14–16] A few case clusters have been described, and person-to-person transmission has been documented on rare occasions.[17,18]

Patients with deficient host defenses, such as those with lymphoreticular malignancy, chronic obstructive pulmonary disease, chronic granulomatous disease, dysgammaglobulinemia, human immunodeficiency virus infection, or receiving corticosteroid therapy, are at high risk for invasive nocardiosis.[5,7,9,13,19–21] Recipients of bone marrow or solid-organ transplants have a particularly high risk. In the latter group, high-dose corticosteroid therapy, a history of cytomegalovirus disease, and high levels of calcineurin inhibitors are independent risk factors for *Nocardia* infections.[22] There are many reports of *Nocardia* infections developing in adults treated with tumor necrosis factor inhibitors, especially infliximab.[23,24]

The host response to *Nocardia* consists of early neutrophil mobilization to localize infection; cell-mediated immunologic mechanisms then supervene, followed by killing of the organism by activated macrophages and cytotoxic T lymphocytes.[25] As a facultative intracellular pathogen, the virulence of *Nocardia* is associated with the ability to inhibit phagosome-lysosome fusion in macrophages and to neutralize phagosomal acidification.[9]

Nocardia causes suppurative necrosis and abscess formation similar to that seen in pyogenic infection. Although tuberculoid granulomas and giant cells have been reported, lesions usually do not demonstrate granulomatous inflammation or tissue fibrosis. Confluent abscesses without capsules are characteristic, which may explain the frequency of dissemination from the primary pulmonary focus. *Nocardia* granules or grains, which are similar to the sulfur granules characteristic of actinomycosis, occasionally are found in superficial *Nocardia* infections but are absent in visceral infections.

Clinical Manifestations

The most common clinical manifestation is pulmonary disease, occurring in more than two thirds of cases. Infection causes acute, subacute, or chronic suppurative disease, which tends to remit and relapse. Acute onset with fever and systemic symptoms is uncommon. Pulmonary infection can manifest with cough or dyspnea and with nonspecific symptoms such as anorexia and weight loss. Hemoptysis occasionally occurs in the setting of cavitary disease.

Untreated pulmonary nocardiosis mimics tuberculosis, with a chronic course that can resolve spontaneously, obscuring the source of subsequent metastatic infection. Chest radiographic findings vary and include bronchopneumonia, alveolar infiltrates, single or scattered nodules or abscesses, and interstitial reticular infiltrates. Cavitation or pleural involvement, or both, can occur.

Widespread dissemination can occur, especially in solid-organ transplant recipients and other immunocompromised hosts. The central nervous system is the most common secondary site, where disease manifests as single or multiple brain abscesses. *N. farcinica* and *N. otitidiscaviarum* have been reported in brain abscesses with increasing frequency, which may have implications for treatment due to their antibiotic resistance patterns.[26–28] *Nocardia* also has been recognized as a cause of persistent neutrophilic meningitis despite negative routine cultures. Neurologic symptoms range from headache to coma with subacute or acute presentations.

Neurotropism is so prominent a feature of nocardiosis that cranial imaging should be performed for patients with pulmonary infection even without the symptoms of central nervous system disease. Computed tomography (CT) or magnetic resonance imaging (MRI) typically shows a necrotic cavity surrounded by a contrast-enhancing smooth capsule of uniform thickness and surrounding edema, in contrast to the more irregular capsule seen in malignant tumors.[26] T2-weighted MRI scans can show multiple concentric rings with various signal intensities.[29]

Skin manifestations of disseminated disease can be indistinguishable from primary cutaneous nocardiosis. Cutaneous lesions include cellulitis, pustules, ulcerations, pyoderma, subcutaneous abscesses, and mycetoma, which is a slowly progressive, often painless granulomatous mass associated with nodules, sinuses, and granules, usually involving the foot. Patients with skin involvement should be evaluated thoroughly to exclude disseminated disease. Subcutaneous abscesses, which are more nodular than fluctuant, do not have the same propensity for fistulous drainage as those caused by *Actinomyces*.[8,30] A cervicofacial syndrome with cervical adenitis due to *Nocardia* has been described in children.[31]

Lymphocutaneous infection caused by *N. brasiliensis* can be indistinguishable from sporotrichosis manifesting as a primary ulcerative lesion at the site of injury, often on the lower extremity, with nodular lymphangitis, and it sometimes is associated with regional adenopathy and mild systemic symptoms.[6,8,30] This syndrome also has been described at the site of a cat scratch.[32]

Nocardia can disseminate to most organs, including kidneys, intestine, pancreas, heart, spleen, liver, joints, bones, eye, spinal cord, thyroid, and adrenal glands.[7,16,20,33,34] Organ infection with *Nocardia* spp. consists of single or multiple nodules or abscesses. Renal infection can cause dysuria, hematuria, or pyuria. *N. brasiliensis* arthritis in a healthy child without a history of penetrating injury was initially treated as juvenile idiopathic arthritis.[35] Nocardia bacteremia is rare, but infections associated with central venous catheters (CVCs) and peritoneal dialysis catheters have been reported. Removal of the CVC followed by 3 months of antibiotic treatment has been successful in these cases.[19,36,37] Limited case reports of nocardiosis in children suggest that clinical presentations are similar to those in adults.

Laboratory Findings and Diagnosis

Nocardia spp. in tissue appear as branching, beaded, gram-positive filaments when stained by the Brown-Brenn modification of the Gram stain or other standard tissue Gram stain and Gomori methenamine-silver stain. *Nocardia* are not visible when stained with hematoxylin and eosin or periodic acid–Schiff stain. Identification in tissue can be confirmed using a modified acid-fast stain because *Nocardia* spp. are acid fast, but other branching, gram-positive rods are not.

Although *Nocardia* grow best on antibiotic-free media, the rate of recovery can be enhanced using selective techniques to suppress rapidly growing organisms in specimens from skin or mucosal sites. Pretreatment with an acid wash and inoculation onto selective buffered charcoal-yeast extract agar (as formulated for the detection of *Legionella* spp.) can increase the recovery of *Nocardia* from respiratory specimens.[38] Although uncommon, *N. asteroides* complex strains can be isolated in automated blood culture systems, especially if patients are receiving immunosuppressive therapy. Performing blind subcultures on day 5 of incubation on negative specimens can increase recovery.[39] When *Nocardia* infection is not suspected, cultures usually are discarded without terminal subculture or too early to allow growth of the organism.

Usual laboratory biochemical methods can be used to differentiate *N. asteroides* complex, *N. otitidiscaviarum* complex, and *N. brasiliensis*; however, phenotypic testing does not identify the many species within the *N. asteroides* complex or the less common human pathogens within the genus.[4,11,40] Definitive identification requires analysis of gene sequences by molecular methods (i.e., 16s rRNA gene and multilocus sequence analysis of 5–7 housekeeping genes have been most successful) and may be necessary for some patients with serious disease.[1,2,4,41–43]

Presumptive identification of a limited number of *N. asteroides* complex isolates can be provided using an abbreviated battery of tests. For example, *N. farcinica* is resistant to ceftriaxone, grows at 45°C, and opacifies Middlebrook agar, whereas *N. cyriacigeorgica* is susceptible to ceftriaxone, imipenem, and amikacin but resistant to ampicillin and erythromycin.[1,44,45] Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry is an emerging method for the identification of species.[46] As the databases expand, full species identifications will be readily and accurately available.

Performance of bronchoalveolar lavage in pulmonary disease or biopsy of an affected tissue site may be necessary when other clinical specimens are nondiagnostic, especially in immunocompromised hosts.

Treatment

Clinical laboratory methods for the susceptibility testing of *Nocardia* spp. are standardized, with breakpoints established for interpretation.[47–48] Although initial selection of antimicrobial therapy must be empiric, primary drug resistance exists. All clinical isolates should be tested.[45,48] In a multisite reproducibility study, end-point determinations were especially difficult for ceftriaxone, imipenem, tigecycline, and sulfonamide. Specific caution for interpreting in vitro testing of *N. cyriacigeorgica* and *N. transvalensis* with ceftriaxone is warranted.[49] Laboratories with little experience should consider sending isolates to reference laboratories for testing.[3]

A retrospective study of more than 750 *Nocardia* isolates sent to the Centers for Disease Control and Prevention from 1995 to 2004 found increasing resistance over time.[50] Among the four most prevalent *Nocardia* species, TMP-SMX resistance ranged from 20% for *N. brasiliensis* to 80% for *N. farcinica*. Linezolid was the only antibiotic to which 100% of the isolates were susceptible. Resistance among all strains tested was lowest for amikacin (5%), imipenem (30%), and ceftriaxone (52%), although *N. farcinica* typically is resistant to the cephalosporins.[3,51] In vitro studies have shown that meropenem is more active than imipenem against most *Nocardia* spp. but less active against *N. farcinica* and *N. nova;* in contrast, most *Nocardia* spp. are resistant to ertapenem.[5,13,52,53]

Amoxicillin-clavulanate is active against many strains of *Nocardia,* except *N. nova, N otitidiscaviarum,* and *N. cyriacigeorgica,* which are resistant.[50–52] Moxifloxacin usually is more active than ciprofloxacin and was shown in one report to be successful in treating a *N. farcinica* brain abscess in an immunosuppressed patient.[54] Data for 1299 clinical isolates confirm the excellent activity of amikacin and linezolid, document increasing resistance to imipenem (51% resistance), and report only 2% of all strains are resistant to TMP-SMX (0.5% resistance for *N. farcinica*).[55]

A sulfonamide always has been the treatment of choice for nocardiosis when used in conjunction with appropriate surgical drainage or excision of empyema or large abscesses. Trimethoprim-sulfamethoxazole (TMP-SMX) is reportedly effective in many clinical series, supplanting sulfonamides as the treatment of choice of many experts.[56] Reports of sulfonamide resistance or lack of effectiveness in immunosuppressed patients led most clinicians to use additional agents in combination with a sulfonamide, at least initially. Nephrotoxic interaction between TMP-SMX and cyclosporine may necessitate the use of alternative agents in organ transplant recipients.[20] Thrice-weekly TMP-SMX used for prophylaxis against *Pneumocystis jirovecii* infections frequently is ineffective in preventing nocardiosis.[19,22]

Because of linezolid's excellent in vitro activity (i.e., minimal inhibitory concentration [MIC] <8 μg/mL for all strains of *Nocardia*) linezolid may be useful as initial therapy until speciation or susceptibility of the isolate is available.[57] Although linezolid is approved only for short courses and is expensive, it has been used for longer-term therapy (with caution that long-term use can have adverse effects). Although clinical improvement can occur with single-drug therapy, two or three drugs with in vitro activity (preferably a combination demonstrating synergy, such as TMP-SMX with amikacin or a carbapenem) should be used for progressive disease, especially in immunocompromised hosts.

Duration of therapy for nocardial infection depends on the site of infection and the immune status of the host. For primary cutaneous nocardiosis, a course of 6 to 12 weeks of sulfonamide therapy is appropriate, although spontaneous resolution of disease without therapy has been reported.[58,59] For patients with isolated pulmonary disease, 6 to 12 months of therapy is preferred.[60] Brain abscess or meningitis requires longer therapy, at least 12 months in most cases. A second or third drug with proven activity in vitro, such as amikacin and ceftriaxone, usually is given for the first 4 to 12 weeks of treatment or until clinical and radiographic improvement is observed.[5,13,60] Parenteral therapy should be used for the first 3 to 6 weeks, until a response to therapy has been documented and the species and its antibiotic susceptibilities have been determined; thereafter, oral therapy can be used to complete the course of treatment.

Relapses after prolonged therapy occur but are uncommon. Lifelong suppressive therapy for nocardiosis is probably prudent in patients with acquired immunodeficiency syndrome and persistent, severe $CD4^+$ T-lymphocyte depletion.[51] Delayed appearance of metastatic abscesses, even during effective therapy, often represents the evolution of a previously seeded focus. Because infection by *Nocardia* can manifest concurrently with infection due to other opportunistic pathogens in immunocompromised patients, poor response to therapy or the development of new lesions should raise the possibility of a concomitant pathogen, such as *Mycobacterium tuberculosis, P. jirovecii,* or *Aspergillus.*

Although older series report mortality rates of 44% to 85%, later published mortality rates range from 15% to 26%.[5,12,20,61–63] Mortality rates for patients with cancer may be as high as 60%. Factors that increase mortality rates include concurrent corticosteroid or antineoplastic therapy and coinfection with cytomegalovirus.[19] Consideration of nocardial infection in the differential diagnosis of immunocompromised or debilitated patients and aggressive diagnostic pursuit can lead to an earlier diagnosis and improved outcome.

Key Points

Epidemiology, Clinical Syndromes, Diagnosis and Treatment of *Nocardia* Infections

Epidemiology

- Ubiquitous soil organisms
- Lung is the primary portal of entry into the body.
- Most infections occur in children with immunodeficiency (e.g., chronic granulomatous disease, HIV infection, chronic high-dose corticosteroid therapy, lymphoreticular malignancies, bone marrow and solid-organ transplantation, and dysgammaglobulinemia).

Clinical Syndromes

- Pulmonary infiltrates or abscesses with or without pleural effusion
- Disseminated disease usually includes pulmonary and central nervous system infection, but any organ can be affected.
- Primary cutaneous or lymphocutaneous infection results from direct inoculation.

Diagnosis

- Tissue diagnosis (e.g., bronchoalveolar lavage, tissue biopsy) often is necessary.
- Branching, beaded, gram-positive filaments using standard Gram staining procedures for tissue or smears
- Modified acid-fast stain confirms identification because *Nocardia* spp. are weakly or partially acid fast, but other branching, gram-positive rods are not.
- Selective media (e.g., selective buffered charcoal-yeast extract agar) may be necessary to prevent overgrowth of more rapidly growing contaminants in specimens from skin or mucosal sites.
- Laboratory personnel should be notified to hold cultures for at least 2 weeks to allow for slow growth of *Nocardia.*
- Definitive species identification requires gene sequencing, although MALDI-TOF mass spectrometry is emerging as a rapid and accurate alternative.
- Standardized methods for in vitro antimicrobial testing are available.

Treatment

- Trimethoprim-sulfamethoxazole (TMP-SMX) has been the historical treatment of choice, but emergence of resistant strains dictates broader coverage.
- Empiric combination therapy is used for pulmonary or disseminated disease, especially in immunocompromised hosts.
  - Two or three active agents are used, including TMP-SMX, linezolid, amikacin, carbapenem, and ceftriaxone.
  - Definitive therapy is guided by in vitro susceptibility tests.

- Surgical debridement as adjunctive therapy is often required
- Duration of therapy for invasive disease is 6 to 12 months or longer.

Escherichia coli

Edwin J. Asturias

Escherichia coli is a genetically diverse species comprising nonpathogenic gut commensals and strains responsible for intestinal and extraintestinal infections in humans.[1] Commensal *E. coli* is the predominant facultative anaerobe of the human gut microbiota, and it colonizes the gastrointestinal tract within hours after birth. *E. coli* is a gram-negative bacillus and oxidase-negative organism of the family Enterobacteriaceae. It grows well aerobically and anaerobically, preferably at 37°C. Approximately 90% of strains ferment lactose and produce indole and cadaverine by means of lysine decarboxylase.

Classic and molecular serotyping is based on the Kauffman classification scheme using the O (somatic) polysaccharides and H (flagellar) surface antigens. Currently, 174 *E. coli* somatic and 53 flagellar antigens are recognized, but only a small subgroup produce disease in humans.[2,3] Pathogenic *E. coli* have evolved various pathotypes (i.e., group of strains of the same species causing a common disease), and multilocus sequence typing (MLST) is a common method for strain typing and establishing relatedness. Before 2011, only few reports of Shiga toxin–producing enteroaggregative *E. coli* (EAEC) causing bloody diarrhea and hemolytic uremic syndrome (HUS) existed, but the outbreak of *E. coli* O104:H4 in Germany proved the plasticity of EAEC and enterohemorrhagic *E. coli* (EHEC) to form a hybrid (EAHEC). Pathogenic *E. coli* virulence factors usually are encoded by large plasmids or chromosomal pathogenicity islands. *E. coli* lacking specific virulence factors also can be opportunistic pathogens of compromised hosts.

Pathogenesis

Enteric Infections

Based on the types of virulence factors and host clinical symptoms, *E. coli* strains are classified as seven major pathotypes for enteric infections: enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enteroinvasive *E. coli* (EIEC, including *Shigella* sp), enteroaggregative *E. coli* (EAEC), and diffusely adherent *E. coli* (DAEC).

ETEC adheres to the small bowel mucosa using one of the fimbrial colonization factor antigens (CFAs), of which more than 25 have been identified, but seven (i.e., CFA/I and CS1–CS6) are considered important. After colonization, ETEC produces one or both of two enterotoxins: heat-labile enterotoxin (LT) and heat-stable enterotoxin (ST).[4–6] Most ETEC express LT alone (27%) or in combination with ST (33%), with variations across regions and populations. LT, a strong immunogen in humans, possesses one A subunit and five identical B subunits. It belongs to the family of AB5 enterotoxins, and they act as adenylate cyclase inducers.

ST shares structural similarity with heat-stable toxins from *V. cholerae* O1/non-O1 and *Yersinia enterocolitica*, and it acts by binding the age-dependent surface membrane receptor guanylyl cyclase type C (GC-C). GC-C stimulation is followed by an increase in intracellular cGMP concentrations, activation of protein kinase A (PKA) or cGMP-dependent protein kinase type II (cGKII) and increased chloride secretion through apical cystic fibrosis transmembrane conductance regulator (CFTR) channels, leading to diarrhea. ST also can induce bicarbonate secretion in a non–cGMP-, non–GC-C-, and non–CFTR-dependent manner.

The phenotypic hallmark of EPEC is its ability to produce attaching and effacing (AE) lesions (Fig. 137.1).[7–9] AE lesions are characterized by actin remodeling of the host cell cytoskeleton and development of a bundle-forming pilus, allowing EPEC to inject intimin (i.e., virulence factor) into the cytosol of enterocytes, causing extensive effacement of the microvilli. Like EPEC, EHEC also adheres to luminal enterocytes and produces AE lesions.[10,11]

EHEC contains a pathogenicity island called the locus of enterocyte effacement (LEE), which is crucial for development of AE lesions. After colonic colonization, EHEC releases one or more toxins related to the Shiga toxin of *Shigella dysenteriae* (i.e., Shiga-like toxin [Stx]) that are cytotoxic to vascular endothelium.

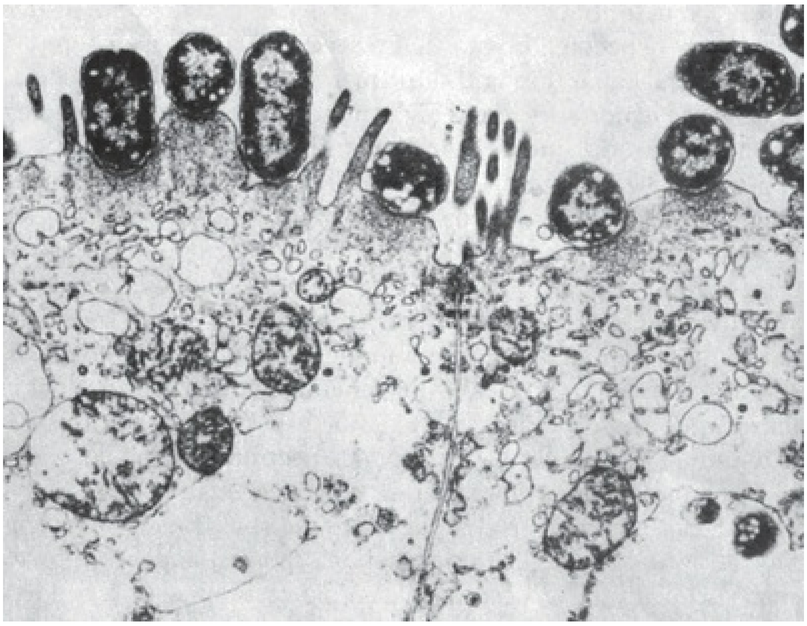

FIGURE 137.1 Electron photomicrograph of the attaching and effacing lesion induced in the gnotobiotic piglet ileum after oral administration of a human enteropathogenic *E. coli* (EPEC) strain. Bacteria are seen intimately attached to the epithelial cells, which respond by forming cup-like pedestals composed of cytoskeletal protein. An identical lesion can be induced by human EHEC strains. (From Baldini MM, Kaper JB, Levine MM, et al. Plasmid-mediated adhesion in enteropathogenic *Escherichia coli*. J Pediatr Gastroenterol Nutr 1983;2:543.)

Similar to EHEC, EIEC can invade colonic enterocytes and spread laterally through the mucosa and lamina propria. EIEC produces secretogenic enterotoxins responsible for the watery diarrhea manifested in most cases. EAEC adheres tenaciously to the intestinal mucosa in a characteristic biofilm. Adherence is mediated by fimbrial organelles called aggregative adherence fimbriae (AAFs). After colonization is achieved, EAEC secretes a series of cytotoxic, secretogenic, and proinflammatory proteins.[12]

Extraintestinal and Disseminated Infections

Extraintestinal infections are primarily urinary tract infections (UTIs) caused by uropathogenic *E. coli* (UPEC) and sepsis or meningitis caused by neonatal meningitis *E. coli* (NMEC).

Uropathogenic *E. coli*

Colonization and adherence are key preceding events in UTI pathogenesis.[13] A typical UTI begins with periurethral contamination by intestinal *E. coli*, followed by urethral colonization and migration to the bladder, which requires appendages such as flagella and pili. UPEC survives by invading the bladder epithelium, producing toxins and proteases to release nutrients from the host cells, and synthesizing siderophores to obtain iron. UPEC binds to uroplakins, the major protein that forms a crystalline array of umbrella cell apical plasma membranes, which protects the bladder. Expressed at the surface of uroepithelial cells, $\alpha_3\beta_1$ integrins also can serve as receptors for UPEC. *E. coli* can then ascend to the kidneys, attaching by adhesins or pili to colonize the renal epithelium and produce tissue-damaging toxins.

The pathogenesis of renal damage by *E. coli* is not fully understood, but direct cellular damage by UPEC hemolysin or direct invasion may be important. By crossing the tubular epithelial barrier, UPEC can access the bloodstream, resulting in bacteremia. UPEC also can form intracellular biofilms called pods, which may promote persistence and relative antibiotic resistance.

Neonatal Meningitis *E. coli*

A distinct extraintestinal pathotype known as NMEC has the ability to survive in blood and invade the meninges of infants.[14] Typical NMEC strains carry the K1 capsular polysaccharide and *sitA* genes with at least two of three other genes: *vat*, *neuC,* and *iucC*. NMEC strains that carry more virulence genes are more invasive to cerebral microvascular endothelial cells. NMEC strains also have a greater ability to produce biofilms.

Epidemiology

Children are especially susceptible to intestinal infection due to *E. coli*. ETEC causes an estimated 280 million cases of diarrhea each year in children younger than 5 years of age and approximately 380,000 deaths mainly due to dehydration. ETEC infection also accounts for 50% to 60% of traveler's diarrhea cases or approximately 60 million cases per year.[15]

For many years, EPEC was considered only second to rotavirus as the most common cause of diarrhea in hospitalized children and responsible for 8% to 10% of outpatient cases of acute gastroenteritis, with important regional and temporal variations. The recent demonstration that EPEC can colonize children asymptomatically, especially those who are breastfeeding, suggests that EPEC requires the interplay of multiple factors to cause diarrhea.

Shiga toxin–producing *E. coli* (STEC) is a foodborne zoonotic agent associated with outbreaks worldwide since it was first identified in 1982. STEC causes hemorrhagic colitis through ingestion of contaminated food or water, including contaminated ground beef, steak, salami, dairy products (e.g., raw milk, cheese, butter, cookie dough), and vegetables (e.g., spinach, lettuce, sprouts). A low infectious dose (i.e., 50–100 colony-forming units) is sufficient to cause disease in humans.

The incidence of STEC infections in the United States in 2012 reported by the Foodborne Diseases Active Surveillance Network (FoodNet) was 0.92 cases per 100,000 people for O157:H7 and 1.43 cases per 100,000 people for non-O157 STEC. In 2013, 87 cases of postdiarrheal HUS were reported among children younger than 18 years of age (0.79 cases/100,000), with half occurring in children younger than 5 years of age (1.55 cases/100,000). The incidence of STEC in other high-income countries varies from 0.4 cases per 100,000 people in Australia to 5.33 cases per 100,000 people in Ireland. Much higher incidences are reported in other middle- and low-income countries such as Argentina and India.

Each year, UTIs affect 150 million people worldwide. In the United States, the cumulative incidence data for UTIs indicate that 3% to 7% of girls and 1% to 2% of boys are diagnosed with a UTI by 6 years of age. UPEC is the most common causative agent for uncomplicated (75%) and complicated (65%) UTIs.[16,17]

NMEC is the main cause of bacterial meningitis in preterm infants and is second to group B streptococci in term neonates. NMEC is sevenfold more frequent among preterm than term infants. Two peaks of infection are recognized: 0 to 3 days, mostly in preterm neonates, and 11 to 15 days in term neonates. Infection rates increase with decreasing birth weight. Most infants with NMEC infections are preterm, and the mortality rate is as high as 33%. A significant increase in multidrug-resistant NMEC strains has been observed recently.[18]

Clinical Manifestations

E. coli remains one of the most common bacterial infections in children. It can manifest as acute gastroenteritis, UTI, bloodstream infection (BSI), and meningitis.

Acute Gastroenteritis

Clinical manifestations of acute gastroenteritis depend on the *E. coli* pathotype. ETEC causes profuse, watery diarrhea and abdominal cramping. Fever, nausea with or without vomiting, chills, loss of appetite, headache, and muscle aches also can occur. The incubation period is 1 to 3 days after exposure and lasts for 3 or 4 days up to 1 week. The severity of ETEC infection usually is less than that of cholera. ETEC is the most common cause of travelers' diarrhea in people of all ages, with onset occurring an average of 7 to 9 days after the start of travel.

EPEC and EAEC usually cause a self-limited, watery diarrhea with a short incubation period of 6 to 48 hours. Nausea, abdominal cramps, and mild fever also can occur. EPEC strains cause diarrhea primarily in nonbreastfeeding children. Persistent diarrhea (>14 days) has been reported with EPEC and especially with EAEC. EAEC is the second leading cause of travelers' diarrhea worldwide. EIEC causes diarrhea that usually is watery, but dysentery develops in a few cases.

EHEC infection characteristically causes hemorrhagic colitis without fever, and it often can be confused with intussusception, inflammatory bowel disease, or ischemic colitis. EHEC infections can evolve to HUS. DAEC causes diarrhea particularly in children. AIEC is the most recently recognized diarrheal pathotype that later was associated with Crohn disease.

Urinary Tract Infection

UPEC is the most common cause of UTIs in children, and risk factors include very young age, no circumcision, constipation, urinary tract anomalies, spinal disorders, and immunodeficiency. In young children, UTI can manifest as fever alone, accompanied by irritability, poor feeding, vomiting, failure to thrive, or jaundice. A UTI should be considered in any infant or child younger than 24 months of age with fever without an apparent source of infection. In older children and adolescents, cystitis typically manifests with dysuria, urgency, and frequency or sometimes with enuresis.

Pyelonephritis often is associated with more severe or systemic symptoms, including fever, back and flank pain, nausea, and vomiting. Ascending infection can result in BSI and systemic inflammatory response syndrome or septic shock (i.e., urosepsis).

Other Extraintestinal Manifestations

Extraintestinal *E. coli* infections can be community-acquired or healthcare-associated infections. NMEC is a major cause of gram-negative neonatal bacterial meningitis in high- and low-income countries. Many of the survivors have neurologic sequelae.

Postdiarrheal Manifestations

Hemolytic Uremic Syndrome

After the characteristic self-limited hemorrhagic colitis, 5% to 7% of EHEC cases develop HUS, which is characterized by the triad of hemolytic anemia, thrombocytopenia, and acute renal failure. HUS is the direct result of the release of Stx, a potent toxin that can enter the systemic circulation through absorption across the epithelium.

Shiga toxin 1 (Stx1) and Shiga toxin 2 (Stx2) are structurally and enzymatically similar but distinct immunologically. Stx1 mimics Stx from *Shigella*, whereas Stx2 shares only 55% of the amino acid sequence, is more potent than Stx1 in humans, and is more commonly associated with hemorrhagic colitis and HUS. Stx binds to the globotriaosylceramide (Gb3) receptor in endothelial cells of the microvasculature of the intestine, kidney, and brain. Formation of a biofilm by some STEC strains (e.g., highly virulent EAEC serotype O104:H4) caused 34 deaths and 908 HUS cases in Germany in 2011.[19]

HUS most commonly occurs in children between 1 and 5 years of age. Oliguria and hypertension are the most common signs of renal injury; seizures, coma, and hemiparesis signal neurologic complications that occur in up to one third of cases.[20] HUS is a nonconsumptive coagulopathy with thrombocytopenia but minimal decrease of clotting factors. Other complications include transient hepatocellular injury in 40% and pancreatitis leading to diabetes mellitus.

Management of HUS requires careful fluid and electrolyte balance and prompt recognition of acute renal failure to prevent fluid overload and lessen hypertension. Antimotility agents should not be administered to anyone with inflammatory or bloody stools or to any child with diarrhea exposed to a person with HUS or hemorrhagic colitis because these drugs are a risk factor for progression of STEC diarrhea. Antibiotics for the treatment of STEC infection are controversial due to induction of the phage lytic cycle and the potential for increased production of Stx. Although some studies have identified an increased risk of HUS with use of trimethoprim-sulfamethoxazole or β-lactam antibiotics, a meta-analysis of all available studies did not reveal a consistent association of antibiotic administration with HUS risk.[21–23]

HUS is a life-threatening disease with a 5% mortality rate. Among survivors, 5% to 10% develop end-stage renal disease or permanent neurologic damage. The duration of *E. coli* O157:H7 shedding seems to be age dependent, with children younger than 5 years carrying the organism for longer periods after the resolution of symptoms.[24] A nondiarrheal form of HUS not associated with Stx of EHEC or *Shigella dysenteriae* type 1 has is caused by the neuraminidase produced by *Streptococcus pneumoniae* infections, which also causes complicated pneumonia.

Inflammatory Bowel Disease

Inflammatory bowel diseases, primarily Crohn disease and ulcerative colitis, are chronic inflammatory disorders of the gastrointestinal tract due to dysfunction of the epithelial barrier with deregulation of the mucosal immune system and the gut microbiota. Some studies postulate a role for AIEC and intestinal dysbiosis in inflammatory bowel disease.[25]

E. coli has been recovered from 65% of chronic lesions in resected ileums of patients with Crohn disease, with strains capable of adherence to buccal cells in vitro. High *E. coli* antigen and antibody concentrations are found in the blood and resected intestinal specimens of Crohn disease patients. The AIEC genome, similar to that of UPEC, encodes type 1 pili. AIEC binding depends on expression of pili on the bacterial surface and on expression of carcinoembryonic antigen–related cell adhesion molecule 6 (CEACAM6) receptors on the apical surface of ileal epithelial cells. CEACAM6 receptors are increased in the ileal mucosa of Crohn disease patients.

AIEC infection also induces the release of tumor necrosis factor-α by macrophages, a key cytokine in bowel inflammation and granuloma formation.[26] In a genetically susceptible host, AIEC may result in permanent changes in the microbiota that can lead to chronic inflammation and inflammatory bowel disease.[27]

Laboratory Findings and Diagnosis

Although the diagnosis of *E. coli* gastroenteritis begins with a routine stool culture, identification of strains belonging to different pathotypes requires proof of expression of one or more group-specific virulence factors. One exception is EHEC O157:H7, which can be distinguished by its inability to ferment sorbitol, yielding colorless colonies on MacConkey agar with added sorbitol. The yield of O157:H7 is substantially higher when stool culture is performed within the first 6 days of diarrheal illness. EHEC (STEC) is now routinely identified by most clinical and public health laboratories by a *stx1* or *stx2* gene using antigen or nucleic acid amplification.

MALDI-TOF mass spectrometry can detect extracted proteins from bacterial cells from growth on primary stool culture and identify all *E. coli* pathotypes to the species level. The FilmArray gastrointestinal panel can simultaneously detect 22 enteric pathogens directly from stool specimens, such as EAEC, EPEC, ETEC, EIEC, and EHEC (i.e., Stx1 and Stx2), including O157:H7 strains. Although more sensitive (95% to 100%), the FilmArray panel has a specificity between 35% and 80% because many *E. coli* detected are associated with copathogens.

UTI diagnosis requires a urinalysis demonstrating evidence of pyuria and a urine culture growing more than 50,000 colony-forming units/mL of *E. coli*.[28,29] Transurethral bladder catheterization or a suprapubic aspirate are the preferred urine collection methods for children. Midstream clean voiding can be used in older children and adolescents.

Treatment

Most *E. coli* diarrheal infections are self-limited and may not require antibiotic therapy. Support of fluid and electrolyte status is the therapeutic priority. If indicated, oral trimethoprim-sulfamethoxazole, azithromycin, or cefixime for 5 days is considered adequate therapy for ETEC, EIEC, EAEC, and EPEC infections.[30–32] Fluoroquinolones are preferable in adolescents and adults. Antimicrobial therapy for ETEC disease is limited by frequent resistance to commonly used antibiotics. Multidrug-resistant *E. coli* strains, a consequence of widespread use of antibiotics in animal and food products, result primarily from β-lactamase production (3% to 36%) and have complicated the therapy of these infections. Extended-spectrum β-lactamases are reported in 15% of cases, and strains can also exhibit chromosomal or plasmid-encoded fluoroquinolone resistance (8% to 40%).

Treatment of UTI should be initiated only when the diagnosis is confirmed. For the febrile young child, empiric therapy may be indicated before urine culture results are final. The goals of treatment of acute UTI are to eliminate the acute infection, to prevent complications, and to reduce the likelihood of renal damage. Oral antibiotic therapy is effective in most children with UTIs. A narrow-spectrum cephalosporin, amoxicillin–clavulanic acid, or trimethoprim-sulfamethoxazole is an appropriate choice, depending on local resistance patterns.

Nitrofurantoin, which is excreted in the urine but has a low therapeutic concentration in the bloodstream, should not be used to treat febrile infants with UTI because it may be insufficient to treat pyelonephritis or urosepsis. Data on short 1- to 3-day courses for febrile UTIs show inferiority to courses of 7 to 14 days; the minimal duration of therapy therefore should be 7 days. UTIs can lead to renal scarring and kidney failure. Since 2011, the American Academy of Pediatrics guidelines for management of a first UTI in children between 2 and 24 months of age recommend performance of a voiding cystourethrogram (VCUG) only for patients with an abnormal renal or bladder ultrasound result.[28,29]

Definitive therapy for septicemia or meningitis due to *E. coli* should be based on in vitro susceptibility tests and the use of bactericidal agents with penetration into the central nervous system. Repeat lumbar puncture is recommended to document eradication of the infecting pathogen. Duration of therapy is based on response and usually is 10 to 14 days for neonates with uncomplicated septicemia and a minimum of 21 days (and at least 14 days after sterilization of cerebrospinal fluid) for meningitis.

Special Considerations

E. coli is on the Centers for Disease Control and Prevention (CDC) list of biologic agents potentially threatening to public health and safety. The *E. coli* O157:H7 strain is recognized as a category B agent because of its food safety hazard and ease of production.

Prevention

Strategies for the prevention and control of the spread of *E. coli* include access to safe water, handwashing and hygiene, decreasing the risk of food contamination, sanitation measures, public education, and vaccination. Exclusive breastfeeding exerts a protective effect against acute gastroenteritis in the first 4 to 6 months of life. Travelers should consume only cooked food and boiled or bottled beverages when visiting developing areas. Prevention of EPEC and EIEC in indigenous populations is best accomplished by improvements in sanitation, food storage, and personal hygiene.

Prevention of EHEC infection has centered on protection of the food supply, especially beef products. Animal carriage of STEC can be diminished by vaccination and improved farm practices. All commercially prepared hamburgers are required to reach an internal temperature of 68°C (155°F), which kills *E. coli*. Hamburgers should be cooked until no pink remains and until juices are clear. Treatment of STEC with antibiotics or toxin-binding agents does not prevent HUS.

Vaccination may be an important primary prevention strategy for humans against the most harmful strains, such as ETEC, UPEC, and NMEC. Despite being a global priority, no effective vaccine is available for the prevention of these infections.[33,34] A patch LT antigen vaccine tested in adult travelers did not fully protect them against ETEC diarrhea in Mexico and Guatemala due to a mismatch in prevalent strains.[35] A vaccine intended to target 80% of ETEC strains globally would require seven or eight colonization factors (i.e., CFA/I, CS1–3, CS4–6, and CS21), assuming the use of an LT toxin component, and it must ensure high levels of mucosal and systemic protection. Vaccines against the K1 capsule on the surface of UPEC and NMEC have not been protective, and the capsular antigen match to host sialic acid has raised concerns about autoimmune reactions similar to previous meningococcal B vaccine candidates.

Klebsiella and *Raoultella* Species

William J. Barson, Amy Leber

Microbiology and Epidemiology

The genus *Klebsiella*, family Enterobacteriaceae, contains at least five *Klebsiella* species and three *Raoultella* species: *K. pneumoniae*, *K. oxytoca*, *K. granulomatis*, *K. variicola*, *K. singaporensis*, *R. terrigena*, *R. ornithinolytica*, and *R. planticola*.[1–6] The two most important human pathogens in terms of frequency and disease severity are *K. pneumoniae* and *K. oxytoca*. *K. pneumoniae* is divided further into subspecies *pneumoniae*, *ozaenae*, and *rhinoscleromatis*. The latter two *K. pneumoniae* subspecies are associated with chronic respiratory tract infections with unusual clinical presentations: ozena, a chronic atrophic rhinitis, and rhinoscleroma, a chronic granulomatous infection of the nose, respectively. These diseases occur most frequently in the tropics.

Subspecies may be difficult to separate from each other and from biochemically inactive strains of *K. pneumoniae* subsp. *pneumoniae*. *K. granulomatis*, formerly known as *Calymmatobacterium granulomatis*, is the agent of granuloma inguinale or donovanosis, a sexually transmitted ulcerative disease of skin and subcutaneous tissues of the genital region (see Chapter 139).

Most *Klebsiella* and *Raoultella* spp. are ubiquitous in nature. They are found in environmental sources such as surface and drinking waters, soil, vegetation, sewage, and industrial waste, and they are associated with mucosal surfaces and diseases of humans, other mammals, birds, and reptiles.[5,7] *K. variicola* is a recently described species that has been isolated from plants and human sources, including the bloodstream. *K. ozanae, K. rhinoscleromatis,* and *K. granulomatis* have been recovered only from human clinical specimens. *Raoultella* spp. are isolated infrequently from human sources. *R. ornithinolytica* and *R. planticola* produce histidine decarboxylase and have been implicated in causing scombroid fish poisoning.[8]

Members of the genera *Klebsiella* and *Raoultella* have properties similar to other Enterobacteriaceae with some distinctive features (see Key Points). Only *R. ornithinolytica* produces ornithine decarboxylase. *Klebsiella* spp. typically use citrate as a sole carbon source, often produce urease, and are positive on the Voges-Proskauer test.[1–6] They are hydrogen sulfide and indole negative, except for *K. oxytoca,* which is indole positive.

K. pneumoniae subsp. *pneumoniae* and *K. oxytoca* usually grow as large, mucoid, lactose-fermenting colonies on MacConkey agar. Commercial and conventional biochemical identification systems can differentiate these two species; the lack of indole production by *K. pneumoniae* is the main identifying feature.

K. pneumoniae is difficult to differentiate from *R. planticola* and *R. terrigena* using basic biochemical tests and commercial identification systems. Studies conducted in Europe have suggested that a significant percentage of organisms identified as *Klebsiella* spp. may be *R. planticola,* but similar studies conducted in the United States suggest that recovery of *R. planticola* is rare.[9,10] Prevalence of these organisms in human disease may vary by geographic location.

Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry has been used for identification of bacterial isolates, has demonstrated overall good performance in the identification of gram-negative bacilli,[11] and can correctly identify and differentiate *Klebsiella* from *Raoultella* spp. Early reports revealed some misidentifications, but supplementation of databases should improve performance.[12,13]

The role of specific virulence factors in the pathogenesis of infection due to *Klebsiella* spp. is unclear, and the importance of different factors may vary by site of infection. Identified virulence factors include cell surface adhesins that may mediate attachment to mucosal surfaces, cell surface capsular polysaccharides and lipopolysaccharide that may inhibit phagocytosis and serum bactericidal activity, and other factors such as siderophores (i.e., iron-chelating compounds), cytotoxins, enterotoxins, and hemolysins.[4,5] Strains of *K. pneumoniae* and *K. oxytoca* that produce enterotoxins and cytotoxins have biologic effects in various animal models of gastrointestinal pathology. Overgrowth of these organisms in the gut of patients receiving antibiotics may lead to gastrointestinal syndromes, including antibiotic-associated colitis.[14]

K. pneumoniae subsp. *pneumoniae* and *K. oxytoca* may be carried in the nasopharynx (1%–6%) and in the intestinal tract (5%–40%) of the general population.[4] Carriage in hospitalized patients and healthcare personnel can be dramatically higher, particularly in the respiratory tract. Airway colonization with *Klebsiella* spp. and other gram-negative bacilli in the mechanically ventilated neonate is a moderate risk factor for bloodstream infections (BSIs) and is associated with severe bronchopulmonary dysplasia.[15]

Clinical Manifestations

Klebsiella spp. are important opportunistic pathogens of children that cause a wide variety of infections, including healthcare- and community-associated BSIs; infections of the central nervous system (CNS), respiratory tract, urinary tract, musculoskeletal system, and peritoneal cavity; and deep abscesses and postsurgical, trauma, and burn wound infections. Approximately 75% of BSIs are healthcare associated.[16–24] Outbreaks in neonatal units are a major concern.[25] Neonatal infections include BSI, meningitis, brain abscess, conjunctivitis, hepatic abscess, endocarditis, pneumonia, necrotizing fasciitis, arthritis, osteomyelitis, urinary tract infection (UTI), and necrotizing enterocolitis (NEC).[26–32] The clinical manifestations of infection are no different from those of other gram-negative bacilli. Although *Escherichia coli* is the most frequent cause of UTI, *Klebsiella* and *Proteus* spp. are also common Enterobacteriaceae organisms associated with UTI.[33]

Gram-negative organisms account for more than 50% of BSIs in children. During a 6-year prospective study of gram-negative BSIs in a pediatric tertiary care medical center in Israel, *K. pneumoniae* was the most commonly identified pathogen, comprising 26% (109 of 419) of isolates.[19] In a review of 57 cases of pediatric BSI caused by *K. pneumoniae*, 67% were younger than 12 months of age, and most had at least one underlying condition, including gastrointestinal tract abnormality in 56%, central venous catheter in 35%, neutropenia in 25%, and urinary tract abnormality in 16%.[34]

The Surveillance and Control of Pathogens of Epidemiologic Importance project based at Virginia Commonwealth University in Richmond has provided important data for identifying the predominant pathogens responsible for healthcare-associated BSIs in children.[35] Although gram-positive organisms, especially coagulase-negative *Staphylococcus* spp., accounted for more than 50% of isolates, *Candida* spp. accounted for 9.3%, and *Klebsiella* spp., *Enterobacter* spp., and *Escherichia coli* accounted for 5.8%, 5%, and 5% of isolates, respectively.

Other conditions associated with *Klebsiella* spp. BSI in childhood include prematurity, prior antibiotic exposure, preceding rotavirus gastroenteritis, Kasai procedure for biliary atresia, malignancy, postoperative status, burns, multiple trauma, acquired immunodeficiency syndrome, granulocyte disorders, homozygous sickle cell disease, solid-organ transplantation, the postoperative period after splenectomy, systemic lupus erythematosus, and interleukin-12 receptor β1 chain deficiency.[19,35–41] Contaminated intravenous solutions also have been identified as a source of *Klebsiella* spp. BSI.[42]

The overall mortality rate for *Klebsiella* spp. BSI is approximately 11%, with a mortality rate of 14.5% for healthcare-associated BSI.[19,35] An increased mortality rate is significantly associated with acute leukemia, neutropenia, healthcare-associated infections (HAIs), and previous corticosteroid therapy.

Cytotoxin-producing strains of *K. oxytoca* have been implicated in antibiotic-associated hemorrhagic colitis.[14,43,44] The clinical manifestations of abdominal pain and bloody diarrhea usually are preceded by antibiotic treatment with a β-lactam agent. Colitis usually is segmental and located predominantly in the right colon. Cessation of the offending antimicrobial agent and supportive care typically result in clinical resolution. Enterotoxigenic and enteroaggregative strains of *K. pneumoniae* also have been implicated as causes of childhood gastroenteritis.[45]

Raoultella spp. have been reported inconsistently as colonizing bacteria of the gastrointestinal tract of hospitalized neonates and as agents of BSI and adult pneumonia.[46,47] *R. planticola* has been isolated from adult urine; wounds, including an intra-abdominal abscess associated with pancreatitis; and contaminated infant formulas.[48–50] *R. ornithinolytica* has been recovered from the blood of a neonate with visceral heterotaxy, functional asplenia, and complex congenital heart disease who had NEC; from one adult with a giant renal cyst; and from another with an enteric fever–like syndrome.[51–53]

R. ornithinolytica and *R. planticola* appear to cause scombroid (histamine) fish poisoning.[8] This condition follows ingestion of improperly stored (>20°C) scombroid fish (e.g., tuna, mahi-mahi, bonito, mackerel, sardine) and results from the breakdown of high concentrations of histidine into histamine by the action of bacterial histidine decarboxylase.[51,53] The incubation period can be 1 minute to 3 hours. Clinical manifestations can include marked skin flushing (especially of the face, upper trunk, and arms), headache, dizziness, abdominal cramps, vomiting, diarrhea, burning of the mouth, urticaria, generalized pruritus, and (rarely) hypotension and bronchospasm.

Therapy

K. pneumoniae and *K oxytoca* frequently are susceptible to the aminoglycosides, carbapenems, third- and fourth-generation cephalosporins, extended-spectrum penicillin/β-lactamase inhibitor combinations, trimethoprim-sulfamethoxazole, and fluoroquinolones; *K. pneumoniae* commonly is susceptible to cefazolin.[54] Both organisms are routinely resistant to ampicillin due to plasmid-mediated β-lactamases such as TEM-1, TEM-2, and SHV-1.[33]

HAIs due to extended-spectrum β-lactamase (ESBL)–producing isolates of *K. pneumoniae* and *K. oxytoca* have emerged.[22,34,35,55–57] The ESBLs are a group of diverse enzymes derived primarily from genes coding for TEM- or SHV-type enzymes by single or multiple amino acid substitutions near the active site of the enzyme.[4,58,59] ESBLs can hydrolyze third-, fourth-, and fifth-generation cephalosporins and monobactams, rendering organisms harboring the enzymes clinically resistant to these agents. However, in vitro

ESBL activity against different β-lactam agents varies, and resistance is not always detected.

β-Lactamase inhibitor combination antibiotics (e.g., piperacillin-tazobactam) can retain some activity in vitro due to inhibition of ESBL by the β-lactamase inhibitor, but reduced susceptibility is typical. Cefepime, a fourth-generation cephalosporin, and piperacillin-tazobactam demonstrate an inoculum effect in vitro, with diminished susceptibility as the inoculum increase from 10^5 to 10^7 organisms. Susceptibility to the cephamycins (i.e., cefoxitin and cefotetan) and carbapenems is maintained.

Genes coding for ESBLs usually are located on transferable plasmids that also can harbor resistance determinants to other antimicrobial agents, including the fluoroquinolones and aminoglycosides.[58,59] In 1998, the incidence of ESBL-producing isolates of *K. pneumoniae* in the United States was about 5% in the National Nosocomial Infection Study system.[4] In another US surveillance network study conducted from 1996 to 2000, the ESBL rates for *K. pneumoniae* and *K. oxytoca* rose from 7% to 9% and 3% to 6%, respectively.[60] Fortunately, ESBL prevalence among organisms isolated from children is considerably lower. The SENTRY Antimicrobial Surveillance Program reported that 1.9% of *E. coli* and 1.1% to 3.2% of *Klebsiella* spp. produced ESBLs.[61] Although TEM-type ESBLs have been prevalent in the United States, CTX-M-type ESBLs have emerged as the predominant ESBL type in many regions of the world and are common in the United States.[62,63] These enzymes preferentially hydrolyze cefotaxime over ceftazidime.

The incidence of ESBLs in *Klebsiella* spp. in the United States varies by institution, mainly because of the isolation of ESBL-positive *K. pneumoniae* in intensive care units and in immunocompromised hosts in tertiary care institutions.[33,55–57] Among 296 pediatric BSI isolates of *E. coli* and *Klebsiella* spp. from hospitalized US children in 1999 to 2003, 35 (12%) produced ESBLs: 17 *K. pneumoniae,* 10 *K. oxytoca,* and 8 *E. coli* isolates. ESBL-producing *Klebsiella* spp. represented 18% of all BSI isolates of *Klebsiella* spp.[64] In this population, risk factors for BSI due to these ESBL-producing organisms were exposure to third-generation cephalosporins in the 30 days before infection, female sex, infection with a *Klebsiella* sp., and corticosteroid use in the 2 weeks before infection. Children with BSI due to these organisms tended to have higher mortality rates and longer lengths of hospitalization compared with children with non–ESBL-producing isolates.

Bacterial strains producing ESBLs may be underdetected because they usually do not demonstrate overt resistance to the third- and fourth-generation cephalosporins and monobactams by standard in vitro laboratory test methods. Detection can be optimized by using screening and confirmatory tests recommended by the Clinical Laboratory and Standards Institute (CLSI).[65] CLSI also established lower breakpoints for the cephalosporins (rather than phenotypic screening among the Enterobacteriaceae) as the primary method for detecting and reporting possible ESBL-producing organisms.[65] For several antibiotics (e.g., cefotaxime, ceftriaxone, ceftazidime, cefepime, aztreonam), the revised or lower minimal inhibitory concentrations (MICs) and larger disk diffusion breakpoints required to categorize an isolate as susceptible allow reporting of susceptibility test results for these agents, obviating the need for screening and confirmatory tests for ESBLs. An additional advantage of the revised breakpoint approach is that it is applicable for detection of ESBLs in all Enterobacteriaceae organisms compared with the traditional screening and confirmation test approach, which is applicable only to *Klebsiella* spp., *E. coli*, and *Proteus mirabilis*.

One of the difficulties in adopting the newer approach is that US Food and Drug Administration (FDA)–cleared commercial antimicrobial test systems currently use the traditional breakpoints. Laboratories desiring to adopt the newer breakpoints must verify the newer breakpoints and devise approaches to reinterpret MIC results from the test systems before reporting. Some commercial systems do not have adequate low-end antimicrobial concentrations to allow interpretation with the revised lower-susceptibility breakpoints. Whatever system is used, it is imperative that laboratories communicate clearly and that physicians interpret susceptibility test results as reported.

In vitro screening tests are no longer recommended for routine use by CLSI, but they may be appropriate for epidemiologic purposes.[65] The phenotypic testing is designed to detect possible ESBL-producing strains of *K. pneumoniae, K. oxytoca, E. coli,* and *P. mirabilis* based on an elevated MIC or a reduced zone of inhibition by disk diffusion testing to select cephalosporins while still falling within traditional interpretative categories of susceptibility. Multiple antimicrobial agents are used in screening tests because in vitro activities of ESBL enzymes vary among β-lactam agents. Failure to identify these strains may lead to a report of false susceptibility to third- and fourth-generation cephalosporins, selection of inappropriate therapy, and treatment failure.

If a screening test suggests the presence of an ESBL, confirmation depends on demonstrating that the activity of one or more antimicrobial agents (commonly ceftazidime and cefotaxime) is enhanced by the addition of clavulanic acid. At least an eightfold decrease in the MIC or a minimum of a 5-mm increase in the zone diameter of inhibition by disk diffusion confirms the presence of an ESBL. If confirmed, the isolate is reported as resistant to all penicillin, cephalosporin, and monobactam agents, with a comment that the organism has been confirmed to produce an ESBL. Although the fourth-generation cephalosporins have greater in vitro activity against these isolates, their clinical efficacy is unclear, and the compounds also should be reported as having resistant organisms.[54–56,58,59] Although the CLSI recommendation is to report the activity of extended-spectrum penicillin/β-lactamase inhibitor combination agents, some consider the use of these agents in treatment of ESBL-positive organisms as ill advised. Until these controversies are resolved, it is prudent not to use these agents as monotherapy for serious infections due to ESBL-producing organisms.

Aminoglycosides, fluoroquinolones, cephamycins, and carbapenems usually maintain activity against ESBL-producing Enterobacteriaceae organisms.[64–68] Amikacin may be the most active aminoglycoside, with susceptibility of 89% of ESBL-producing *E. coli* and *Klebsiella* spp.[64] Fluoroquinolone resistance among *Klebsiella* spp. causing UTI ranges from 4.2% to 7.8%, with 80% of ESBL-producing *E. coli* and *Klebsiella* spp. susceptible to ciprofloxacin.[64,68] Resistance has developed after the use of cephamycins due to loss of porin channels that are responsible for cephamycin entry into the cell, and there is little clinical experience demonstrating their efficacy. The carbapenems retain full activity against ESBL-producing isolates and should be used for treatment of serious infections.[66,67]

Klebsiella spp. can harbor other plasmid-mediated β-lactamases, including AmpC β-lactamases, similar to the chromosomal enzymes commonly found in *Enterobacter* spp., inhibitor-resistant TEMs, and carbapenemases. The AmpC β-lactamases are not inhibited by clavulanic acid and other β-lactamase inhibitors, and extended-spectrum penicillin/β-lactamase inhibitor combination antibiotics and the cephamycins usually are ineffective. The fourth-generation cephalosporins and carbapenems retain activity.[4,58–61,69]

Perhaps most alarming is the emergence among Enterobacteriaceae organisms of carbapenem resistance due to carbapenemases. Organisms harboring these enzymes have been responsible for many HAIs worldwide.[70–73] The most common carbapenemases among Enterobacteriaceae are the *K. pneumoniae* carbapenemases (KPCs), first identified in the United States in a *K. pneumoniae* isolate in North Carolina.[74] Most reports of infections due to KPC-positive organisms are from metropolitan centers in the northeast, but they increasingly are reported throughout the United States. The KPCs constitute a group of similar enzymes (i.e., serine carbapenemases) that can be found in *K. pneumoniae, K. oxytoca, E. coli, Citrobacter freundii, Enterobacter* spp., and other gram-negative bacilli, but the enzymes occur most frequently in isolates of *K. pneumoniae*. The KPCs confer resistance to all of the carbapenems and to all generations of cephalosporins.

Although β-lactamase inhibitors such as clavulanic acid and tazobactam demonstrate some inhibition of KPCs, inhibition usually is not sufficient to render extended-spectrum penicillin/β-lactamase inhibitor combination antibiotics active against these organisms. However, a novel β-lactamase inhibitor, avibactam, with increased potency and an expanded spectrum of inhibition of ESBLs, Amp C β-lactamases, and KPCs is promising.[75]

CLSI published updated susceptibility test interpretive criteria for the Enterobacteriaceae, with lower MIC and higher disk diffusion breakpoints to define isolates susceptible to the carbapenem antibiotics, including ertapenem, meropenem, imipenem-cilastatin, and doripenem.[76] The revised breakpoints are designed to better identify organisms that may be harboring carbapenemases but would not be reported as intermediate or resistant with use of older breakpoints. Laboratories may choose to continue to use screening and confirmatory tests with the older breakpoints to identify carbapenemase-producing

Enterobacteriaceae in much the same way as using screening and confirmatory tests for detection of ESBLs. *Raoultella* spp. exhibit antibiotic susceptibility patterns similar to those of *Klebsiella* spp.[48]

The recommended confirmatory test for carbapenemase production is the modified Hodge test.[76] The test is performed on an agar plate, and carbapenemase activity in a test organism is demonstrated by the ability of the enzyme to inactivate a carbapenem antibiotic, allowing a carbapenem-susceptible indicator *E. coli* organism to show enhanced growth in the presence of the antibiotic. Biochemical-based detection kits are available to screen bacterial isolates for resistance, and the use of MALDI-TOF has been investigated as a possible method for detection of carbapenemases.[77–79]

Empiric treatment for the seriously ill patient with suspected HAI due to a *Klebsiella* spp. or other gram-negative bacilli should include the combination of meropenem and amikacin. For patients with BSI (including those with granulocytopenia or hypotension) or other serious infections due to these organisms, combination therapy with a β-lactam antibiotic plus an aminoglycoside to which the organism is susceptible is reasonable.[80,81] Fluoroquinolones and piperacillin-tazobactam have been used to treat serious infections caused by *Klebsiella* spp. that were resistant to the aminoglycosides and cephalosporins.[82,83] Unfortunately, resistance to these agents also is reported, and definitive antimicrobial therapy must be guided by the results of susceptibility testing.

For meningitis due to antibiotic-susceptible *Klebsiella* spp., a third-generation cephalosporin and aminoglycoside administered intravenously is the regimen of choice. In one study of children 4 days to 7 months old who were receiving cefotaxime and amikacin parenterally, the mean duration of positive cerebrospinal fluid (CSF) cultures was 5.8 ± 4.7 days (range, 2–15 days).[80] Five of these patients also received 1 to 25 doses of intraventricular amikacin; however, intraventricular instillation is not recommended in children who do not have a central nervous system device in place. The efficacy of treatment for children with gram-negative bacillary meningitis should be monitored by repeated examinations and CSF cultures. Patients with prolonged positive cultures may be candidates for meropenem if supported by susceptibility testing. Therapy should be continued for at least 2 weeks after the first sterile CSF culture or for a total course of at least 21 days, whichever is longer.

Management recommendations for infections associated with intravascular devices due to *Klebsiella* spp. and other members of the Enterobacteriaceae family usually have included the removal of the foreign body. For device-associated BSI due to gram-negative bacilli, an attempt to treat with antibiotics without device removal is reasonable if the patient is clinically stable and the bloodstream is sterilized quickly (<72 hours).[84] Duration of therapy is 10 to 14 days after blood stream sterilization, if the device is retained. If the device is removed, 10 days should be adequate. Oral cephalosporins, trimethoprim-sulfamethoxazole, or fluoroquinolones can be considered for treatment of UTIs due to susceptible organisms.

Treatment of infections due to carbapenem-resistant Enterobacteriaceae organisms may be problematic because they are resistant to all β-lactam antibiotics and can be resistant to the aminoglycosides (50% to gentamicin and amikacin) and fluoroquinolones (98%).[85] Additional antibiotic susceptibility testing should be performed for tigecycline, colistin or polymyxin B, aztreonam, ceftazidime-avibactam, and fosfomycin (for urinary tract isolates). The newer agent tigecycline, the revived agent colistin, and the investigated ceftazidime-avibactam may offer therapeutic options.[75,86,87] Combination therapy with two or more agents is recommended for the treatment of infections due to carbapenem-resistant members of the Enterobacteriaceae family because of the associated high mortality rate, concern about emergence of resistance during monotherapy, and lack of clearly effective monotherapy.[87]

Prevention

A 24-valent *K. pneumoniae* capsular polysaccharide vaccine is immunogenic in patients who have sustained trauma, a group known to be at risk for serious infection with gram-negative bacteria.[88] Prevention of *Klebsiella spp.* infection predominately correlates with prevention of HAIs (see Key Points Box in Chapter 139). In the future, active immunoprophylaxis may be a consideration for people at risk for infections caused by *Klebsiella* spp. and other gram-negative bacilli.

Key Points

Diagnosis and Management of *Klebsiella* and *Raoultella* Infection

Microbiology

- Members of the Enterobacteriaceae family, the catalase-positive, oxidase-negative, gram-negative bacilli are facultative anaerobes that reduce nitrate to nitrite and ferment glucose and other carbohydrates. They are nonmotile, usually encapsulated, and usually produce lysine but not ornithine decarboxylase.

- They grow well on blood, chocolate, and usually MacConkey agar, often producing a large, mucoid, lactose-fermenting colony on the latter.

- *Klebsiella* spp. can produce extended-spectrum β-lactamases (ESBLs) and AmpC-type β-lactamases, and *K. pneumoniae* carbapenemases (KPCs) have emerged.

- Organisms are identified by biochemical methods or MALDI-TOF mass spectrometry. Susceptibility testing performed by automated and manual methods is standard. Revised Clinical and Laboratory Standards Institute breakpoints optimize screening for enzyme-resistance mechanisms.

Epidemiology

- The organisms are ubiquitous in nature (i.e., soil and water), contaminate healthcare environments and personnel, and colonize mucosal surfaces.

Clinical Importance

- *Klebsiella spp*. are important pathogens in a wide variety of infections, including healthcare- and community-associated bloodstream infections (BSIs); central nervous system (CNS), respiratory tract, and urinary tract infections (UTIs); and postoperative, trauma, and burn wound infections in neonates and children.

- Cytotoxin-producing *K. oxytoca* is implicated in antibiotic-associated hemorrhagic colitis; enterotoxigenic and enteroaggregative *K. pneumoniae* are potential causes of childhood gastroenteritis.

- *Raoultella ornithinolytica* and *R. planticola* are associated with scombroid fish poisoning and rarely cause BSIs.

- Organisms are recovered in culture using standard laboratory procedures.

Treatment

- Organisms are susceptible in vitro to and usually treatable with aminoglycosides, carbapenems, first-generation and extended-spectrum cephalosporins. and penicillin/β-lactamase inhibitor combinations.

- ESBL-producing strain infections can be treated with a carbapenem; amikacin is added for serious infections.

- Infections with AmpC-type β-lactamase–producing strains can be treated with a carbapenem or a fourth-generation cephalosporin; an aminoglycoside is added for serious infections.

- Infections with carbapenemase-producing strains can be treated with combination therapy of two or more drugs based on the results of susceptibility testing for tigecycline, colistin, aztreonam, and ceftazidime-avibactam; fosfomycin can be tested for urine isolates.

Duration of Therapy

- Uncomplicated UTI: 7- to 10-day course usually is adequate; removal of a catheter hastens eradication.

- Infection of CNS: minimum of 2 weeks after documented sterilization.

- Intravascular device–associated BSI: removal of the device (attempt to treat without removal is possible if the patient is clinically stable and the bloodstream is sterilized <72 hours); minimum of 10- to 14-day course of antibiotics after documented sterilization if the device is retained; shorter duration if device removed.

Special Considerations

- Multidrug-resistant infections should be managed in consultation with an infectious diseases specialist.

- Patients colonized or infected with a multidrug-resistant pathogen should be cared for under contact isolation conditions.

- Hospital-associated infections can be minimized by strict attention to hand hygiene, limiting the use of invasive devices, antimicrobial stewardship, and use of infection control bundles during placement of invasive devices. Use of ethanol locks in certain populations requiring long-term venous access can decrease the incidence of recurrent central line–associated BSIs.

Klebsiella granulomatis: Granuloma Inguinale

Bradley P. Stoner

Granuloma inguinale, or donovanosis, is a chronic, slowly destructive, ulcerative disease of skin and subcutaneous tissues caused by *Klebsiella* (formerly *Calymmatobacterium*) *granulomatis*.[1,2] Uncommon in industrialized countries, donovanosis historically has been seen among adolescents and adults in some tropical and developing regions, including Papua New Guinea, central Australia, South Africa, Brazil, and regions of India.[3–7] Sporadic cases also have been reported in the West Indies, South America, and other areas of southern Africa. Children rarely are diagnosed with donovanosis.[8,9]

In recent years, several endemic regions have reported substantial declines in prevalence,[10–12] and case reports from developed countries often involve people who have migrated from endemic areas.[13–15] The published literature on donovanosis represents few geographic locations, reflects limited microbiologic testing, and relies on syndromic genital ulcer disease surveillance in areas where donovanosis is thought to be most common.[16] Increased awareness of the role of genital ulcer disease in human immunodeficiency virus (HIV) transmission may raise public health interest in donovanosis.[17,18]

The sexual transmission of donovanosis has been controversial, but there is substantial evidence that *K. granulomatis* is transmitted sexually.[16,19] Transmission rates of up to 52% have been reported among steady sexual partners of those with donovanosis.[8] Although rare, vertical transmission of donovanosis has been reported.[20] There also is evidence that transmission can occur through fecal contamination.[21]

Clinical Manifestations

Donovanosis lesions involve the genitalia (typically the prepuce or glans in men and the vagina or labia minora in women) in 80% to 90% of cases but also can involve the inguinal and anal regions (Fig. 139.1A and B). Beginning as a small papule or multiple papules at the site of inoculation, donovanosis typically manifests with painless, easily bleeding ulcers or vegetative lesions (see Fig. 139.1C), which can be ulcerogranulomatous, hypertrophic, necrotic, or sclerotic.[22] Ulcerative lesions expand slowly and become clean, shallow, well-demarcated ulcers with a beefy red granular base (see Fig. 139.1D). Prominent lymphadenopathy often develops, leading to further ulceration of overlying skin.[23] In most cases, clinical findings suggest donovanosis but are not highly specific.[8,19,24]

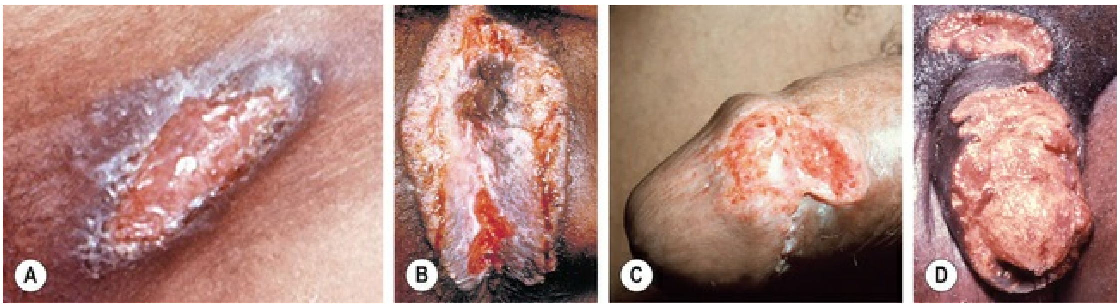

FIGURE 139.1 Lesions in patients with donovanosis. (A) Healing inguinal ulcer. (B) Perianal skin ulcer. (C) penile ulcer. (D) Penile ulcer with extensive tissue damage. (From Centers for Disease Control and Prevention's Public Health Image Library. http://phil.cdc.gov/phil/home.asp.)

Untreated lesions can cause extensive local tissue damage, including pelvic and perianal fistulas, urethral obstruction, and lymphedema.[19] Although uncommon, lesions can develop secondary bacterial infection and cellulitis. Systemic infections can cause fever, weight loss, and anemia. Involvement of the bone, joint, and liver occurs infrequently and is likely more common in pregnant women. Involvement of the head and neck also has been described.[25] Unusual manifestations in HIV-infected patients have also been reported, including penile autoamputation and malignant transformation to squamous cell carcinoma.[26,27]

The differential diagnosis of donovanosis includes syphilis, lymphogranuloma venereum, chancroid, lymphoma, carcinoma, tuberculosis, blastomycosis, and other granulomatous diseases. People suspected of having donovanosis should have a thorough examination and should be tested for syphilis and other sexually transmitted infections, including HIV, which can coexist with donovanosis.[19,26–28] The increased risk of HIV transmission associated with genital ulcer disease (e.g., syphilis, herpes simplex virus infection, donovanosis) underscores the importance of prompt recognition and treatment.[17]

Laboratory Diagnosis

K. granulomatis is a pleomorphic, intracellular, gram-negative bacterium. Although difficult to grow on artificial media, *K. granulomatis* can be identified using tissue crush or biopsy specimens. For tissue crush specimens, granulation tissue is collected from a lesion and crushed between two microscopic slides. After excess material has been removed from the ulcer base with a cotton swab, the first swab collection is most sensitive.[16,22]

Donovan bodies, which look like safety pins clustered in macrophages when stained with Wright or Giemsa stain, are diagnostic of *K. granulomatis.* A polymerase chain reaction test for *K. granulomatis* is available for use in some research settings but is not available commercially.[29,30] Light microscopy is a less reliable diagnostic technique for donovanosis.[8,24,31]

Treatment and Management

Prompt identification and treatment are important for optimal management.[32] However, in most donovanosis-endemic areas, diagnostic testing is limited, and treatment is determined by syndromic algorithm. The syndromic algorithm should be evaluated routinely to determine whether donovanosis therapy should be included in the genital ulcer disease treatment provided.

Initiation of antibiotic therapy slows progression of lesions, but prolonged therapy usually is required for effective treatment. Several antimicrobial regimens are effective, but few controlled trials have been published. Although doxycycline has historically been the treatment of choice for donovanosis, accumulating evidence supports the use of azithromycin as the preferred first-line agent.[33,34] European treatment guidelines recommend azithromycin given orally as 1 g weekly or 500 mg daily for adults and as 20 mg/kg once daily for children.[22] Updated treatment guidelines from the US Centers for Disease Control and Prevention (CDC) also recommend azithromycin administered as 1 g weekly or 500 mg daily.[35] Alternative regimens include doxycycline (100 mg PO twice daily), ciprofloxacin (750 mg PO twice daily), erythromycin base (500 mg PO four times daily), and trimethoprim-sulfamethoxazole (one double-strength (160 mg/800 mg) tablet PO twice daily).

Recommendations for the duration of antimicrobial therapy vary. The CDC recommends treatment for at least 3 weeks and until all lesions have healed completely. Some specialists recommend the addition of an aminoglycoside (e.g., 1 mg/kg of gentamicin IV every 8 hours) if clinical improvement is not evident within the first few days of antibiotic therapy.[35]

Clinical studies suggest an incubation period for donovanosis of 1 to 8 weeks or longer.[8,22] Contact intervals are not standardized. The CDC treatment guidelines recommend that sex partners within 60 days before the onset of the patient's symptoms be examined and offered therapy. However, the value of empiric therapy in the absence of clinical signs and symptoms has not been established.[22,35]

Because doxycycline and ciprofloxacin are contraindicated in pregnant women (and pregnancy is a relative contraindication to the use of sulfonamides), pregnant and lactating women should be treated with a macrolide regimen (i.e., azithromycin or erythromycin). Judicious addition of an aminoglycoside may also be considered.

Few data exist regarding preferred treatment regimens and clinical outcomes of HIV-infected patients. One study found no difference in the duration of ulcer healing and rate of recurrence between HIV-infected and uninfected pregnant women.[36] The CDC treatment guidelines recommend that people with granuloma inguinale and HIV infection should receive the same regimens as those who are HIV uninfected. However, patients should be monitored closely for relapse or treatment failure, and if failing the initial antimicrobial therapy, an aminoglycoside (e.g., gentamicin) can be added.[35]

The risk of complications, such as complete genital erosion and urethral obstruction, can be minimized with early therapy. If extensive tissue destruction has occurred, surgery may be required.[37] Relapse is common, especially if the duration of treatment is inadequate, and can occur 6 to 18 months after apparently effective therapy.

Prevention and Control

Few data exist regarding effective prevention and control. Prevention should be part of a broad sexually transmitted infection prevention and control program, with emphasis on providing information about risks and complications of sexually transmitted infections (including HIV), safer sex practices, early recognition and treatment of sexually transmitted infections, and sex partner evaluation and treatment.[6,23,35]

Enterobacter, *Cronobacter*, and *Pantoea* Species

Dennis J. Cunningham, Amy Leber

Microbiology and Epidemiology

The genera *Enterobacter, Cronobacter,* and *Pantoea* are all members of the Enterobacteriaceae family. The genus *Enterobacter* has undergone significant taxonomic revision. Although there are more than 15 named species, molecular techniques likely will identify additional species.[1–9] Many former members of this genus have been transferred to other genera in the family Enterobacteriaceae, including to *Klebsiella, Serratia, Hafnia,* and *Pantoea* genera. Some have been transferred to new genera, including to *Lelliottia, Pluralibacter,* and *Kosakonia*.[2]

The genus *Pantoea* has been proposed to accommodate several isolates with significant biochemical and nucleic acid diversity that formerly were included in the heterogeneous taxon called the *Enterobacter agglomerans* group.[10] There are more than 20 species, with *P. agglomerans* and *P. ananatis* most associated with human infections. Some commercial biochemical identification systems include *P. agglomerans* or *P. agglomerans* group in their databases, but they may not differentiate correctly among *Pantoea* species.

The *Enterobacter* spp. most commonly recovered from human sources include *E. cloacae, E. aerogenes,* and to a lesser extent, *Pantoea* (formerly *Enterobacter*) *agglomerans* group, *Cronobacter* spp., *E. gergoviae,* and *E. asburiae*. *E. cloacae* is by far the most common clinical isolate. A number of newly named species (formerly included in the *E. cloacae* group) are difficult to differentiate by biochemical test methods.[1–5] Organisms formerly classified as *E. sakazakii* comprised a diverse group and are renamed as *Cronobacter* spp., which comprise at least seven named species, of which *C. sakazakii* and *C. malonaticus* are most frequently isolated from human infections. Some commercial biochemical identification systems use the terms *E. cloacae* group and *C. sakazakii* group to describe these closely related and difficult to distinguish organisms.

Improved identification methods are needed. Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry demonstrates overall good performance in the identification of gram-negative bacilli.[11] It shows promise for differentiating among *Enterobacter, Cronobacter,* and *Pantoea* species.[12–14]

Enterobacter, Cronobacter, and *Pantoea* spp. are nonfastidious in nature and grow on blood and chocolate agar and selective media for enteric bacteria. On MacConkey agar, *E. cloacae* and *E. aerogenes* commonly appear as pink, lactose-fermenting, mucoid colonies similar in appearance to *Klebsiella pneumoniae* and *K. oxytoca.* Most isolates of *Cronobacter* spp. and *P. agglomerans* group organisms produce a nondiffusible, yellow pigment, which often is more intense when grown on enriched media at 25°C versus 35°C. Colonies of *Cronobacter* can appear dry, wrinkled, and leathery on some media.

Most isolates of *Enterobacter* spp. are motile, use citrate as a sole carbon source, and give a positive Voges-Proskauer test result but do not produce indole or hydrogen sulfide. With the exception of the *P. agglomerans* group organisms, most isolates have ornithine decarboxylase activity. Motility and ornithine reactions help to differentiate *Enterobacter* spp. from the common human isolates of *Klebsiella* spp.

Commercial or conventional biochemical identification systems usually perform well for identifying and differentiating *E. cloacae, E. aerogenes, P. agglomerans,* and *Cronobacter* spp., but the other species present a greater challenge and are not all represented in the databases of commercial systems. A report of *Enterobacter* spp. or *Cronobacter* spp. may be sufficient for most clinical purposes, although knowledge of the specific species is important in the setting of a potential nosocomial outbreak or when the clinical significance of the isolate is questioned.

Enterobacter spp. and *Pantoea* spp. are common inhabitants of the gastrointestinal tract of humans and other mammals, and they can be found in water, sewage, soil, plant material, and foods. Even the more common human isolates, *E. cloacae* and *E. aerogenes,* have been described as having a ubiquitous animal and environmental distribution. *Pantoea* spp. are commonly associated with plants or are well-known agents of disease in plants.

In humans, *Enterobacter* spp. and *Pantoea* spp. are opportunistic pathogens and are among the most common causes of nosocomial pneumonia, urinary tract infection, surgical wound infection, and catheter-related bloodstream infection (BSI). These organisms frequently colonize the skin and respiratory, urinary, and gastrointestinal tracts of hospitalized patients. These sites act as portals of entry for localized or invasive disease.[1–5] *Enterobacter* spp. and *Pantoea* spp. also cause community-acquired urinary tract, skin, soft tissue, and other infections, although at much lower rates than other gram-negative bacilli such as *E. coli, Proteus* spp., and *Klebsiella* spp. Community-acquired infections due to *P. agglomerans* have been associated with foreign bodies and with plant thorn and wood splinter injuries.

Enterobacter spp. accounted for 5% of all bacterial pathogens and 9% of gram-negative bacilli in more than 4000 episodes of nosocomial or community-acquired BSIs in North America and Latin America in 1997.[15] Of almost 75,000 gram-negative bacilli recovered from BSIs in patients in intensive care units (ICUs) in the United States between 1993 and 2004, *Enterobacter* spp. accounted for 14% of isolates.[16]

Two US studies indicate that *Enterobacter* spp. represent the fourth and seventh most common pathogens causing BSI in pediatric ICUs (PICUs) and neonatal ICUs (NICUs), respectively.[17,18] A 2003 US study of ICU nosocomial bacterial infections reported that *Enterobacter* spp. accounted for 10%, 4%, 9%, and 7% of pneumonia, BSI, surgical site, and urinary tract infections, respectively, due to gram-negative bacilli.[19] *Enterobacter* spp. also accounted for 15% of all gram-negative BSIs in children in Israel.[20] An outbreak of *E. gergoviae* among adult kidney transplant recipients was associated with a common source of contamination, which was presumed to be urinary catheters or stents.[21]

An endogenous source of *Enterobacter* spp. is most common in nosocomial infections. Approximately 40% of infants are fecal carriers of *Klebsiella* or *Enterobacter* spp. on discharge from NICUs. Colonization in nursery settings has been associated with overcrowding, inadequate handwashing, low birth weight, prematurity, endotracheal intubation, prolonged hospitalization, contaminated infant formula or parenteral nutrition fluid, and the use of antibiotics or central venous catheters (CVCs). Risk factors for infection include immunosuppression from any cause, prematurity, use of devices (e.g., CVC, endotracheal tube, urinary catheter), and prior use of antibiotics. The role of microbial virulence factors in the pathogenicity of these organisms has been reviewed.[5]

Clinical Manifestations

BSI is the most common form of invasive infection due to *Enterobacter* spp.[6–9,22,23] Signs and symptoms in children are similar to those due to other gram-negative enteric bacteria. Fever occurs in 83% to 87% and hypotension or shock in 8% to 28% of patients. Leukocytosis or leukopenia can develop, and mortality rates for children range from 6% to 24%.

Lower respiratory tract infection, including pneumonia with BSI, is the second most common pediatric infection due to *Enterobacter* spp. In pediatric national nosocomial surveillance studies, *Enterobacter* spp. were the third and fourth leading causes of nosocomial pneumonia in PICUs and NICUs, respectively, rising from 7.4% in 1992 to 13% in 1997.[17,18] Pneumonia due to *Enterobacter* spp. occurs more often in infants younger than 2 months of age than in older infants and children.

Other *Enterobacter* spp. infections in infants and children include meningitis, brain abscess, endocarditis, pyogenic arthritis, and peritonitis. *Klebsiella* or *Enterobacter* spp. accounted for 16% of meningitis cases due to gram-negative enteric bacteria during a 21-year period in Dallas.[24] *Enterobacter* spp. also are associated with nosocomial gastrointestinal, urinary tract, surgical site, eye, ear, nose, and throat infections (Table 140.1).[17,18]

TABLE 140.1

Pediatric *Enterobacter* spp. Infections Reported by the National Nosocomial Infections Surveillance System

Infection	Percentage of Cases	
	Neonatal ICU	Pediatric ICU
Bloodstream	2.9	6.2
Gastrointestinal tract	5.5	ND
Pneumonia	8.2	9.3
Lower respiratory tract other than pneumonia	ND	12.2
Urinary tract	ND	10.3
Surgical site	7.6	8.1
Eye, ear, nose, throat	4.5	ND

ICU, intensive care unit; ND, no data.

Data from Andresen J, Asmar BI, Dajani AS. Increasing *Enterobacter* bacteremia in pediatric patients. Pediatr Infect Dis J 1994;13:787–792; Delétoile A, Decré D, Courant S, et al. Phylogeny and identification of *Pantoea* species and typing of *Pantoea agglomerans* strains by multilocus gene sequencing. J Clin Microbiol 2009;47:300–310.

Cronobacter spp. have particular importance in young infants because of an association with powdered infant formula feeding[25] and because of a propensity for causing necrotizing enterocolitis and meningitis in a fashion similar to *Citrobacter koseri* (see Chapter 141). *C. sakazakii* is the only member of the genus that can use sialic acid, and this may contribute to its association with neonatal infections because sialic acid is found in breast milk, infant formula, the gastrointestinal tract, and the brain.[26]

Neonatal meningitis due to *Cronobacter* is associated with a high prevalence of brain abscess or cyst formation, high mortality rate (40% to 80%), and long-term neurologic sequelae in survivors. There is controversy about whether the intracerebral cystic lesions visualized on computed tomography (CT) in neonates with *Cronobacter* meningitis result from infarction leading to sterile liquefaction cysts or from abscess formation. *Cronobacter* has been isolated from brain cysts, suggesting a need to obtain cyst aspirates for Gram stain and culture if possible. When *Cronobacter* is recovered from neonatal blood or cerebrospinal fluid (CSF) culture, serial CT or magnetic resonance imaging studies should be performed to evaluate brain cyst or abscess formation to guide optimal management.[27] The World Health Organization has recommended preparation guidelines and continued improvement of powdered infant formula manufacturing processes to reduce this mode of acquisition of *Cronobacter* spp.[25]

Pantoea agglomerans is an uncommon human pathogen. It has been reported to cause BSIs, including neonatal BSI related to administration of contaminated intravenous solutions, and has been associated with contamination of indwelling catheters. Septic shock, respiratory failure, and death occurred in 7 of 8 patients in one outbreak related to contaminated parenteral fluid.[28] Another study reported 5 sporadic cases of *Pantoea agglomerans* BSI in preterm neonates over a 2-year period at one hospital; no source was identified.[29]

Inflections can be polymicrobial, making the role of *Pantoea* difficult to determine.[30] Other reported infections include peritonitis during chronic ambulatory peritoneal dialysis, suppurative arthritis, skin and soft tissue infections presumably resulting from medical devices, a foreign body, and a plant thorn injury during rose gardening[31,32] *Pantoea* spp. endophthalmitis developed in a patient after ocular trauma while using a lawn mower; a metal fragment was found lodged in the lens of the eye.[33]

Treatment

Antibiotic susceptibility patterns for *Enterobacter* spp. vary between centers and among species, making monitoring of antimicrobial susceptibility patterns critical. *Cronobacter* spp. and *E. gergoviae* may be susceptible to ampicillin, cefazolin, and other narrow-spectrum cephalosporins, but *E. cloacae, E. aerogenes,* and several other *Enterobacter* spp. are uniformly resistant to these agents.[34]

E. cloacae, E. aerogenes, and other selected Enterobacteriaceae, including *Citrobacter freundii, Proteus vulgaris, Morganella morganii, Serratia* spp., and *Providencia* spp., harbor a chromosomal gene (*ampC*) coding for AmpC-type β-lactamase production.[35] Frequently produced at low levels on initial laboratory isolation, high-level production is induced after in vitro or in vivo exposure to selected β-lactam antibiotics, particularly compounds such as ampicillin, first- or second-generation cephalosporins, and clavulanic acid.

Initial isolates can appear susceptible to extended spectrum β-lactam agents by in vitro test methods, particularly rapid susceptibility test methods. AmpC β-lactamase production can be stably de-repressed in these organisms due to a chromosomal mutation of the *ampD* gene that normally plays a role in repressing *ampC* gene transcription. These strains, referred to as *stably de-repressed mutants*, can emerge during selective antimicrobial pressure within days of starting a course of β-lactam therapy and produce high levels of AmpC β-lactamase constitutively.[34–36]

Emergence of resistance appears to occur more often in *Enterobacter* spp. than in other enteric bacteria known to harbor *ampC* genes.[36] High-level AmpC production renders the organism resistant to many β-lactam antibiotics, including third-generation cephalosporins and extended-spectrum β-lactam/β-lactamase inhibitor combination drugs. Susceptibility to fourth-generation cephalosporins and carbapenems is retained.

No routine procedures are recommended by the Clinical Laboratory and Standards Institute (CLSI) for laboratory detection of inducible AmpC-mediated resistance in *Enterobacter* spp. and related organisms. A double-disk approximation test can be used, in which a known AmpC inducer antibiotic disk and an indicator antibiotic disk are placed in adjacent positions on a lawn of a test organism. A measurable reduction (i.e., flattening) in the zone of inhibition on the side of the indicator antibiotic disk adjacent to the inducer antibiotic disk suggests AmpC production.[37] An alternative approach is a disk diffusion test format similar to the CLSI confirmation disk test for the presence of extended-spectrum β-lactamases (ESBLs). (see Chapter 138).[38]

In areas where inducible AmpC resistance is common, it seems prudent to report *E. cloacae* and other known AmpC producers as resistant to third-generation cephalosporins and extended-spectrum β-lactam/β-lactamase inhibitor combination drugs or at least to caution against their use as monotherapy for serious infections.[39] It is equally important to repeat testing of secondary isolates of *Enterobacter* spp. and other gram-negative bacilli recovered from normally sterile body sites when recovered 24 to 48 hours after commencing appropriate antibiotic therapy.

Enterobacter spp. can contain plasmids encoding for ESBLs and other genes coding resistance to other classes of antibiotics.[3] In a

North American and Latin American survey of gram-negative BSIs in which 399 *Enterobacter* spp. isolates were tested, meropenem, imipenem, and cefepime were the most active agents; more than 99% of isolates were susceptible. The fluoroquinolones and aminoglycosides also had good activity; 90% to 96% of isolates were susceptible. No other antibiotic demonstrated activity for more than 78% of isolates.[15]

Optimal antibiotic therapy for infections due to *Enterobacter* spp. is unclear. For serious infections, it may be prudent to avoid the use of a single-agent, extended-spectrum cephalosporin or a β- lactam/β-lactamase inhibitor combination other than a fourth-generation cephalosporin because of possible rapid selection of resistance. Addition of an aminoglycoside is reasonable for a serious infection outside the central nervous system (CNS). For treatment of meningitis, meropenem is the optimal choice, and many experts add an aminoglycoside in this setting.[40–42] For patients with type I hypersensitivity reactions to β-lactams, use of a fluoroquinolone plus an aminoglycoside may be effective.

Careful monitoring of the patient's clinical course, particularly for occurrence of CNS complications, is essential, especially with *Cronobacter* infection. Appropriate specimens must be obtained sequentially to demonstrate a sustained bacteriologic response. Prompt removal of contaminated prosthetic devices is essential to eradicate the organism and effect a cure. Failure to remove these devices compromises a rapid bacteriologic response and increases the likelihood that resistant organisms will emerge.

Good handwashing technique and assiduous application of other infection control practices are essential to prevent nosocomial transfer of organisms. The use of broad-spectrum antimicrobial agents should be strictly limited; unnecessary antimicrobial therapy should be avoided.

Key Points

Diagnosis and Management of *Enterobacter* Species Infections

Microbiology

- Members of Enterobacteriaceae: facultative, gram-negative bacilli that are catalase positive and oxidase negative, reduce nitrate to nitrite, and ferment glucose and other carbohydrates

- Indole negative; most species are motile and usually are encapsulated.

- Good growth on blood, chocolate, and MacConkey agar (usually); often produce large, mucoid colonies that are pink, indicating lactose fermentation

Epidemiology

- Common inhabitants of the gastrointestinal tract of humans and other mammals; found in water, sewage, soil, plant material, and foods

- *Enterobacter aerogenes* and *E. cloacae* are the most common clinically encountered species.

- Important pathogen in a wide variety of infections, including the bloodstream, central nervous system, and respiratory and urinary tracts; substantial cause of nosocomial infections

- Risk factors include foreign bodies and medical devices, neutropenia, and immunosuppression.

Diagnosis

- Recovery in culture using standard laboratory procedures

- Identification by biochemical methods or MALDI-TOF; susceptibility testing by automated or manual methods

Treatment

- Many species have intrinsic low-level resistance to third-generation cephalosporins and β-lactam–β-lactamase inhibitor combination drugs.

- An infectious diseases consultation is prudent when treating patients with *Enterobacter*, *Cronobacter*, or *Pantoea* infection. When selecting antimicrobial agents for empiric therapy, local antibiograms can help to guide the decision.

- Therapy with third-generation cephalosporins or β-lactam/β-lactamase inhibitor combinations should be avoided because these agents can induce *ampC* resistance.

- Meropenem is the drug of choice for meningitis. Some experts add an aminoglycoside.

- Cefepime plus an aminoglycoside is an effective combination therapy for serious infections outside the central nervous system.

- In patients allergic to cefepime, a fluoroquinolone plus gentamicin may be reasonable therapy.

Duration of Therapy

- For patients with meningitis, treatment is 4 to 6 weeks after cerebral spinal fluid sterilization is documented.

- For patients with bacteremia and no foreign body, treatment is 2 to 3 weeks after sterilization of the blood is documented.

- For patients with persistent bacteremia or when a foreign body is not removed, the duration of therapy is 4 to 6 weeks after sterilization of the blood is documented, but it may not be curative.

Citrobacter Species

Stella Antonara, Monica I. Ardura

Microbiology and Epidemiology

The genus *Citrobacter* has undergone significant taxonomic revision through the use of newer techniques based on DNA relatedness. The genus contains 11 named species: *Citrobacter freundii, C. koseri* (formerly *C. diversus*), *C. amalonaticus, C. youngae, C. farmeri, C. braakii, C. werkmanii, C. sedlakii, C. gillenii, C. murliniae,* and *C. rodentium.*[1–5] All species except *C. rodentium* (pathogenic for mice) have been recovered from human clinical specimens. However, *C. freundii* and *C. koseri* and *C. braakii* are the most important human pathogens. *C. freundii*, *C. koseri*, and *C. amalonaticus* appear to be distinct organisms, but only *C. koseri* appears to be genetically homogeneous. Several other named species form a closely related group and are difficult to differentiate biochemically; they are sometimes referred to as *C. freundii* complex organisms.

Citrobacter spp. are gram-negative bacilli in the family Enterobacteriaceae. They ferment glucose and other carbohydrates, are catalase and oxidase positive, and reduce nitrate. Most isolates are motile and use citrate as a sole carbon source, but they lack urease and lysine decarboxylase activity. Production of hydrogen sulfide varies, occurring in *C. freundii* and a few other species. On *Salmonella-Shigella* agar, lactose-negative and hydrogen sulfide–positive isolates of *Citrobacter* spp. produce black colonies resembling those of *Salmonella* spp. The lysine decarboxylase reaction allows separation of the hydrogen sulfide–producing isolates of *Citrobacter* spp. from *Salmonella* spp.[1–5]

Selected isolates of *C. freundii* have O (somatic) cell wall antigens closely related to the O antigens of *Salmonella* spp. and therefore cross-react with *Salmonella* typing antisera.[1] Rare isolates of *C. freundii* and *C. braakii* cross-react with some commercial *Escherichia coli* O157 typing antisera. For this reason, it is always prudent to confirm the identification of suspected *Salmonella* spp. and *E. coli* O157 by the use of biochemical and serologic methods. Identification of *Citrobacter* species also can be successfully achieved by the use of proteomic methods such as matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry.[6,7] Any limitation in the identification of rarely encountered species depends on the inclusion of those species in the system's database.

Citrobacter spp. primarily are inhabitants of the intestinal tract of mammals and other vertebrates. Their isolation from environmental sources such as water and soil likely is the result of fecal excretion. *Citrobacter* spp. are not common agents of human disease, and most often are recovered from stool as colonizing flora of the gastrointestinal tract. When associated with significant human infection, *Citrobacter* can be recovered from blood, cerebrospinal fluid (CSF), urine, respiratory tract secretions, and wounds. The most common *Citrobacter* spp. isolated from human sources are *C. freundii* (all sites previously listed), *C. koseri* (all sites but most commonly the CSF and brain), *C. amalonaticus* (all sites except CSF), *C. braakii* (primarily stool), and *C. youngae* (primarily stool).[2]

The pathogenesis of infection has not been fully characterized. Most *C. koseri* isolates produce hemolysins, are piliated, and are resistant to killing by pooled human sera. The proclivity to cause central nervous system (CNS) infection and particularly brain abscesses is not well understood. Tropism for the CNS may be associated with specific outer membrane proteins. In one study, 79% of strains of *C. koseri* isolated from CSF had a unique 32-kd outer membrane protein, which was found in only 9% of isolates from other kinds of specimens.[8] *C. freundii* invades and replicates within brain microvascular endothelial cells in vitro.[9] *C. koseri* can enter macrophages, survive phagolysosomal fusion, and replicate intracellularly in the neonatal rat model; infected macrophages can then infiltrate blood vessels in the brain, starting the process leading to brain abscess formation.[1,10] Myeloid differentiation primary response gene 88 *(MYD88)*–dependent pathways in primary astrocytes are crucial for the induction of an inflammatory response and containment of *C. koseri* in CNS infection.[11]

In the pediatric population, infections occur most commonly in neonates.[12,13] Organisms can be transmitted by vertical transmission from mothers or by nosocomial spread, although most are considered sporadic cases from an unknown source. Direct mother-to-infant transmission has been confirmed by ribotyping and DNA fingerprinting.[14,15] It is likely that individual strains circulating in the community periodically gain access to a hospital nursery from the hands of nursery personnel and visitors.[14,16,17] One nursery outbreak of *C. freundii* was traced to contaminated infant formula.[18]

Clinical Manifestations

Citrobacter spp. are opportunistic pathogens in humans that can lead to invasive disease, including infections of the urinary tract, respiratory tract, CNS, skin, and soft tissue. The bacteria can cause osteomyelitis, suppurative arthritis, bacteremia, endocarditis, endophthalmitis, and intra-abdominal infections, particularly in neonates and immunocompromised hosts.

In infants, sepsis and meningitis are the most common clinical manifestations of infection.[12,13] Bacterial sepsis is associated with meningitis in about one half of cases. From 1969 to 1989 in Dallas, TX, *Citrobacter* spp. accounted for 9% of 91 cases of gram-negative enteric meningitis in infants 1 day to 2 years of age.[19] *C. koseri* was responsible for 90% of cases, and *C. freundii* caused most of the remaining cases. Neonatal sepsis and meningitis can manifest as early-onset (<1 week of life) or late-onset (>1 week of life) disease and can be fulminant or insidious. In 2002 and 2003, *Citrobacter* spp. caused 2.9% of early-onset sepsis in very low birth weight infants.[20]

No early features distinguish meningitis due to *Citrobacter* spp. from meningitis due to other gram-negative rods. Approximately 80% of infants with meningitis due to *Citrobacter* spp. develop one or more intracerebral abscesses (Fig. 141.1). In contrast, less than 10% of cases of infants with meningitis due to other gram-negative organisms have associated abscesses.[12,13] Neonatal brain abscesses also can occur with infections caused by *Cronobacter* (formerly

Enterobacter) *sakazakii, Proteus mirabilis,* and *Serratia marcescens*. In a contemporary review of brain abscesses in children, intracranial abscesses caused by *Citrobacter* spp. were more frequent compared with historical cohorts and occurred solely in neonates.[21] Brain abscesses can evolve any time during the acute course, including several weeks after commencement of treatment.

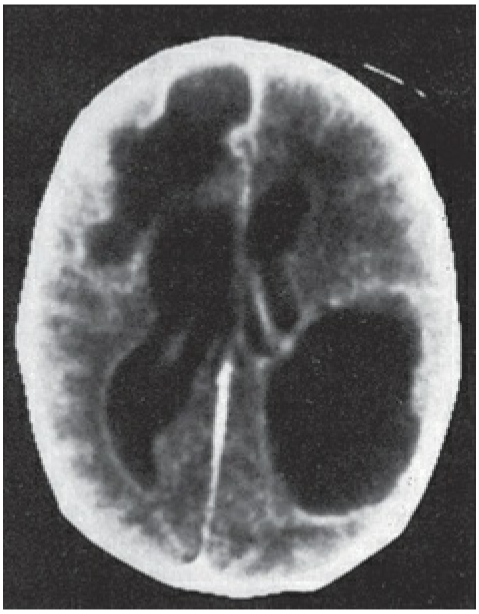

FIGURE 141.1 Computed tomography of a neonate with multiple brain abscesses caused by *Citrobacter koseri*.

The prognosis for meningitis due to *Citrobacter* spp. in neonates is poor. Approximately 30% to 35% of infected infants die, and only 15% to 20% survive with a structurally normal brain at completion of therapy; however, data on long-term prognosis are limited.[12] Although at least 40% of survivors show some form of developmental delay or physical impairment, or both, there are reports of infants with brain abscesses due to *Citrobacter* spp. who develop normally.[22]

Other *Citrobacter* spp. infections in infants occur rarely. Gastroenteritis, osteomyelitis, pyogenic arthritis, pulmonary infections, and pneumatosis intestinalis have been described.[13] In older children, adults, and immunocompromised hosts, *Citrobacter* spp. is associated most commonly with urinary tract, bloodstream, intra-abdominal, skin, soft tissue, and respiratory tract infections.[23]

Citrobacter spp. are the cause of urinary tract infection (UTI) in less than 3% of adults and children.[24,25] In a review of 37 pediatric cases, the mean age was 6.9 years, with a range of 1 month to 18 years.[24] Females predominated, and 56% of patients had underlying urinary tract or renal anomalies or neurologic impairment. Presenting symptoms were similar to those of UTI from other causes, including dysuria, fever, incontinence, frequency, flank pain, and hematuria. *C. freundii* accounted for 71% of cases, and *C. koseri* for the remainder. UTIs involving *Citrobacter* spp. and other enteric bacilli occurred in about 25% of patients.

In immunocompromised patients, *Citrobacter* spp. causes bacteremia but rarely leads to CNS disease. *C. freundii* caused 2.3% of bloodstream infections in the first year after lung transplantation in 190 pediatric patients.[26] Infections in immunocompromised patients more frequently are caused by multidrug-resistant strains.[23,27–29] Eye infections, including keratitis and endogenous and traumatic endopthalmitis caused by *Citrobacter* spp., have been reported.[30–32] An outbreak of severe gastroenteritis associated with several cases of hemolytic uremic syndrome occurred in a nursery school.[33] The source of this outbreak was sandwiches prepared with green butter containing a toxigenic strain of *C. freundii*. The butter had been made with contaminated parsley grown in an organically fertilized garden.

Treatment

Most data on in vitro antimicrobial susceptibility and therapeutic management are for infections due to *C. freundii* and *C. koseri*. These organisms can harbor a wide variety of β-lactamases. Both species are resistant uniformly to ampicillin, and *C. freundii* is also resistant to first-generation cephalosporins. *C. freundii* and some other *Citrobacter* spp. harbor chromosomal AmpC-type β-lactamases that can inactivate third-generation cephalosporins (see Chapter 140).[34] This enzyme is not inhibited by β-lactamase inhibitors such as tazobactam or clavulanate. A US national surveillance study of hospital-associated bloodstream infections reported resistance patterns for 23 *C. freundii* isolates.[35] Resistance to piperacillin, piperacillin/tazobactam, ceftriaxone, and ceftazidime occurred commonly (39%–48%); 96% of the ceftazidime-resistant isolates were susceptible to cefepime.

Some strains of *C. freundii* also harbor extended-spectrum β-lactamases and *Klebsiella pneumoniae*–type carbapenemases (KPCs) that are found more commonly in *Klebsiella* spp. (see Chapter 138). These plasmid-mediated enzymes are problematic because they are readily transferred from one strain to another in a healthcare environment.[36,37]

Citrobacter spp. usually are susceptible to fourth-generation cephalosporins such as cefepime (compared with third-generation cephalosporins such as ceftriaxone or ceftazidime) due to relative stability to inactivation by AmpC enzymes. Emergence of cefepime resistance in a clinical C. *freundii* strain due to a novel plasmid-mediated AmpC-type β-lactamase has been reported.[38] The carbapenems typically are active. *C. koseri* susceptibility to trimethoprim-sulfamethoxazole and the aminoglycosides varies. Among 117 *Citrobacter* spp. from US hospitals in 2007, the rates of susceptibility to the agents listed were 100% for meropenem and imipenem, 98% for cefepime, 95% for ceftriaxone, 86% for ceftazidime, 94% for piperacillin/tazobactam, 96% for gentamicin, 95% for tobramycin, and 97% for ciprofloxacin and levofloxacin.[39] In an antimicrobial surveillance study examining 776 *Citrobacter* species collected between 2008 and 2012 using the revised Clinical and Laboratory Standards Institute (CLSI) breakpoints for carbapenems, there was no significant change in the sensitivity of imipenem (97.1%), ertapenem (97.7%), meropenem (98.8%), and doripenem (98.9%).[40] Multidrug-resistant isolates may be susceptible to colistin, polymyxin B, and tigecycline.[41]

Optimal antimicrobial therapy for *C. koseri* meningitis has not been established, but a combination of a third- or fourth-generation cephalosporin plus an aminoglycoside to which the organism is susceptible is reasonable.[13] Monotherapy with high-dose cefotaxime or ceftriaxone or with imipenem-cilastatin has been successful.[42,43] Meropenem seems a logical carbapenem choice due to less potential for neurotoxicity. With recognition of the possible role of intracellular *C. koseri* in the pathogenesis of cerebral abscesses and possible poor CNS penetration of aminoglycosides, treatment with a third-generation cephalosporin in combination with ciprofloxacin has been used successfully.[44]

In infants with meningitis, a repeat lumbar puncture after 24 to 48 hours of antibiotic therapy should be performed to ensure CSF sterility. Neuroimaging should be obtained for all neonates with invasive *Citrobacter* infections. Neurosurgical drainage of abscesses has been used with various degrees of success. For patients with an accessible brain abscess, neurosurgical drainage is recommended if clinically feasible. For children who have progressive hydrocephalus and fibrous compartmentalization of the ventricular space, instillation of intraventricular urokinase also has been performed.[45] In the presence of CNS abscesses, cultures of CSF should be performed regularly until sterility is documented. Meningitis without abscess formation usually is treated for a minimum of 21 days after the first sterile CSF culture. For intracranial abscesses, a 4- to 6-week course from initial sterile CSF cultures is the minimal duration usually recommended, depending on clinical and radiologic improvement.[12,13] Testing for hearing loss and neurologic and developmental delays should be performed in all infants with *Citrobacter* spp. CNS infection.

Prevention of infections due to *Citrobacter* spp. is related predominantly to preventing healthcare-associated infections. Strict cohorting of infected or colonized neonates is prudent but may not effectively control nursery outbreaks. Meticulous handwashing is mandatory.

Acknowledgment

We acknowledge the substantial contributions of D.W. Powell and M.J. Marcon to this chapter in previous editions.

Key Points

Diagnosis and Management of Infections With Citrobacter Species

Microbiology

- Catalase-positive, oxidase-negative, gram-negative rod
- Lactose fermenting on MacConkey media
- Chromosomal AmpC-producing; resistant to ampicillin and first-generation cephalosporins

Epidemiology

- Normal enteric flora; also found in the environment
- In infants <2 months, proclivity for CNS disease, including meningitis and brain abscesses
- Most cases are sporadic; vertical and horizontal transmission are described.
- Outbreaks support person-to-person transmission.

Diagnosis

- *C. koseri* is recovered easily in cultures from CSF samples, without use of specialized media.
- Use of PYR disk can differentiate atypical *Citrobacter* species (positive) from *Salmonella* species (negative).
- MALDI-TOF can differentiate *Citrobacter* spp. from other Enterobacteriaceae.

Treatment

- A combination of surgical and antimicrobial therapy typically is used.
- Empiric therapy with a third- or fourth-generation cephalosporin plus an aminoglycoside is common but depends on local antimicrobial susceptibility data.
- Targeted therapy should be guided by antimicrobial susceptibilities of the clinical isolate.

Duration of Therapy

- Duration of therapy for meningitis is similar to that for other enteric gram-negative neonatal pathogens.
- Prolonged therapy (4–6 weeks after documented CSF

sterilization) is required for brain abscesses and is guided by clinical and imaging improvement.

Less Commonly Encountered Enterobacteriaceae

Joshua R. Watson, Rebecca Wallihan, Stella Antonara

Microbiology, Epidemiology, Clinical Manifestations, and Treatment

More than 99% of the Enterobacteriaceae family of bacteria recovered in clinical laboratories belong to a few dozen species. Three species—*Escherichia coli, Proteus mirabilis,* and *Klebsiella pneumoniae*—make up more than 90% of isolates, and several other well-recognized species account for most of the remaining clinical isolates.[1] Some less common genera have well-described, clinically important member species, whereas others are newly described genera with species that have rarely been reported to cause human infections.[1–6]

Many newly described species were formerly classified as atypical members of recognized species or by various group designations, such as enteric group organisms, with a numeric designation. DNA relatedness and 16S ribosomal RNA gene sequencing studies have allowed the placement of these organisms into new genera. No single commercial identification system includes all of these species in its database. It may be appropriate for laboratories to report such organisms with questionable identities as *Escherichia coli*-like or *Enterobacter*-like and to refer the isolate to a reference laboratory for definitive identification when clinically warranted.

Antibiotic susceptibility testing should produce reliable in vitro results because the organisms are members of the family Enterobacteriaceae, for which standardized test methods are available.[7] The taxonomic classification of newly described organisms will evolve as additional genetic relationships are discovered. Similarly, our understanding of their true clinical significance will improve as better laboratory identification methods become available.[7]

Buttiauxella species.

Buttiauxella encompasses at least seven species—*B. agrestis*, *B. ferragutiae*, *B. gaviniae*, *B. brennerae*, *B. izardii*, *B. noackiae*, and *B. warmboldiae*—which include environmental, nonhuman strains and opportunistic human pathogens.[2,4,8] Identification can be performed with biochemical methods, 16S rDNA sequencing, and proteomic methods such as matrix-assisted laser desorption ionization (MALDI).[9]

Case reports describe wound infection and urinary tract infection (UTI) with *Buttiauxella*.[9,10] A new class of chromosomal inducible β-lactamases was reported in a clinical *Buttiauxella* isolate from a skull wound infection.[11]

Cedecea species.

The genus *Cedecea* includes *C. davisae*, *C. lapagei*, *C. neteri*, and several unnamed species.[2] *Cedecea* was first discovered at the Centers for Disease Control and Prevention (CDC), and its name is derived from the letters CDC. Strains of *Cedecea* spp. have biochemical reactions similar to those of *Serratia*, including lipase positivity and resistance to polymyxin B, but they lack deoxyribonuclease and gelatinase activity.

Cedecea spp. are rare human pathogens, with most infections reported for adults with underlying conditions, including diabetes mellitus, malignancy, heart disease, and chronic renal disease. *Cedecea* has been isolated primarily from the bloodstream, respiratory tract, peritoneal fluid, or associated with soft tissue infections. There are at least 8 reported cases of bloodstream infection (BSI) due to *Cedecea* spp.: *C. davisae* (5), *C. neteri* (2), and *C. lapagei* (1) in a patient with a cement-related chemical burn wound.[6,12–14] Although *Cedecea* spp. have been isolated from the feces of hospitalized children, there are no reported cases of pediatric infection.[15]

Treatment of *Cedecea* infections can be challenging due to antibiotic resistance. Isolates resistant to extended-spectrum cephalosporins, aminoglycosides, and carbapenems have been reported due to AmpC β-lactamases (i.e., class C or group 1) combined with porin deficiency.[6,12,16,17]

Edwardsiella species.

Organisms of the genus *Edwardsiella* are found in freshwater environments and cold-blooded animals, including fish, reptiles, and amphibians, but they occasionally are found in birds and mammals. *E. tarda*, *E. hoshinae*, *E. ictaluri*, and *E. piscicida* are the four recognized species of this genus, but only *E. tarda* has been associated with human disease.[1–6] *Edwardsiella* spp. usually are positive for lysine and ornithine decarboxylase activity, but they yield a negative Voges-Proskauer test result and do not use citrate as a sole carbon source. Most clinical isolates of *E. tarda* produce hydrogen sulfide on *Salmonella-Shigella* agar plates and do not ferment lactose. Further testing is required to exclude *Salmonella* spp.[1–6]

E. tarda is not considered to be part of the normal human intestinal flora because it is recovered in less than 1% of stool samples in colonization studies. Human infections usually result from exposure to the organism in its natural environments.

A variety of human infections due to *E. tarda* are described, but none has been associated with outbreaks or epidemics of disease.[18–26] Infections can be divided into intestinal and extraintestinal forms. Multiple clinical and epidemiologic investigations suggest that *E. tarda* is a true enteropathogen because it is isolated from stool cultures significantly more frequently in people with diarrhea than those who are asymptomatic.[1,2] Intestinal infections due to *E. tarda* usually manifest as acute secretory enteritis associated with consumption of raw seafood or snake flesh or with other aquatic exposures. Although gastroenteritis typically is self-limited, intestinal infections in immunocompromised patients can be severe, and fatal cases of *E. tarda* diarrhea have been described.[26]

Extraintestinal infections include septicemia and meningitis; wound infections such as cellulitis, myonecrosis, and gas gangrene; cholecystitis; peritonitis; intra-abdominal, hepatic, and tubo-ovarian abscesses; prosthetic valve endocarditis; pyogenic arthritis; and osteomyelitis.[1,18–22,27–29] Wound infections are the most important *E. tarda* infections and usually occur after local trauma, such as abrasion, laceration, or penetrating injury. Wound infections also have been associated with aquatic injuries and often represent combined infection with *Aeromonas hydrophila*,[1] although *E. tarda* has been isolated as the sole pathogen in many cases.[27] Invasive infection most commonly occurs in adults with underlying conditions, including hepatobiliary disease, malignancy, and diabetes mellitus. In children, sickle cell anemia has been linked to serious infections due to *E. tarda,* as it has been with *Salmonella* spp.[11,18,28] Osteomyelitis and meningitis have occurred in individuals with hemoglobinopathies and chronic granulomatous disease, and myonecrosis has been reported in an immunocompetent host.[27,30]

Although the precise pathogenesis is unknown, the gastrointestinal tract is presumably the site of *E. tarda* colonization, with invasion leading to BSI and subsequent focal infection. Case reports suggest that *E. tarda* in neonates may be acquired from the mother.[20,29]

E. tarda is commonly resistant to colistin and polymyxin B. In serious invasive infections, combination therapy with an extended-spectrum cephalosporin and an aminoglycoside has been successful. Antibiotic therapy for gastroenteritis due to *E. tarda* usually is not indicated in immunocompetent hosts.

Ewingella americana.

Ewingella americana is the only species in the genus *Ewingella*. Biochemically, this organism is similar to *Pantoea agglomerans*, but it does not use arabinose.[2] Infrequent reports of *E. americana* infections include bacteremia, peritonitis, pneumonia, exacerbation of chronic obstructive pulmonary disease, conjunctivitis, and Waterhouse-Friderichsen syndrome in adults with underlying medical conditions.[6,31] A case of conjunctivitis due to *E. americana* was reported for a 3-year-old immunocompetent child.[32] *E. americana* caused a number of cases of pseudo-BSI due to contamination of blood culture bottles by the use of nonsterile citrated blood collection tubes in a children's hospital.[33] Multidrug resistance has been reported.[31,34]

***Hafnia* species.**

Hafnia alvei was the only named species of the genus *Hafnia*, although organisms currently classified as *H. alvei* can be separated into three distinct genospecies.[35] A new species, *Hafnia paralvei,* was created for the former members of *H. alvei* genogroup.[2] Both species can be isolated from clinical specimens, but *H. alvei* is likely more toxigenic.[1,36] Unlike *E. tarda, H. alvei* is found commonly in feces of humans and animals, in sewage, and in soil. Several reports suggest that *H. alvei* is one of the most frequently recovered members of the family Enterobacteriaceae in the human gastrointestinal tract. Organisms can be recovered on routine enteric media such as MacConkey agar and appear as colorless colonies similar to *Salmonella* or *Shigella* spp.[2] *H. alvei* also appears similar to *E. coli* O157 on sorbitol-MacConkey agar because both organisms commonly are D-sorbitol negative and appear as colorless colonies. *H. alvei* is lysine decarboxylase and ornithine decarboxylase positive and is positive in the Voges-Proskauer test.[3]

H. alvei is an uncommon cause of human infection, and its role remains unclear in many cases because it is often recovered concomitantly with more virulent organisms. It has been implicated as a cause of gastroenteritis in adults and children, but the evidence is not convincing.[35] Extraintestinal infections include BSI, meningitis, UTI, keratitis, endogenous endophthalmitis, wound infection, intra-abdominal abscess, and empyema in immunocompromised patients, although infection has been reported in immunocompetent hosts.[37–42] In a case of chorioamnionitis and preterm birth, *H. alvei* was detected by 16S rDNA sequencing from a vaginal specimen.[43]

Most infections in adults are healthcare related and associated with underlying medical conditions. Reports of extraintestinal infections in children between 7 days and 13 years of age include bacteremia, meningitis, UTI, and hepatic abscess after liver transplantation.[41,42,44] In contrast to adults, many children with *H. alvei* infections did not have identifiable comorbidities.[42] *H. alvei* can harbor chromosomal AmpC β-lactamases.

Kluyvera **species.**

The genus *Kluyvera* includes four species: *K. cryocrescens, K. ascorbata, K. georgiana,* and *K. cochleae. Kluyvera* spp. are phenotypically similar to *E. coli* but are citrate positive.[2] Found in water, soil, sewage, and healthcare environments, most human infections result from *K. ascorbata*.[45] Reports of *Kluyvera* infections in children describe a range of clinical presentations, including UTI, BSI (including catheter-associated infections), diarrhea, peritonitis, neonatal meningitis and sepsis, skin and soft tissue infection, pneumonia, and emphysematous gastritis.[45–47] *Kluyvera* spp. also have been implicated in opportunistic infections of immunocompromised patients, specifically diarrheal disease in adults with neutropenia.[45]

Chromosome-encoded genes in *Kluyvera* spp. are thought to be the progenitors of CTX-M enzymes, which are plasmid-mediated, extended-spectrum β-lactamases of growing concern for infections caused by Enterobacteriaceae.[48] A multidrug-resistant *K. ascorbata* causing septicemia and a *Klebsiella pneumoniae* carbapenemase (KPC)–producing *K. georgiana* causing pneumonia have been described.[49,50]

Leclercia adecarboxylata**.**

L. adecarboxylata was previously known as *Escherichia adecarboxylata* on the basis of its similarity to *E. coli* but with negative decarboxylase reactions.[2] *Leclercia* has been isolated from environmental sources, including food and water.[51] In immunocompetent and immunocompromised adults, *Leclercia* has been recovered from various sites, including blood, wounds, peritoneal fluid, synovial fluid, and a dental and parapharyngeal abscess.[52,53] In many cases, *Leclercia* was a component of mixed bacterial growth.[53] A few reports of skin and soft tissue infections were water related, including fresh and salt water.[54]

Reports of *Leclercia* infections in children are rare and include BSI, neonatal sepsis, cellulitis, and a peritoneal dialysis-related infection.[55,56] BSI with an extended-spectrum β-lactamase–

producing *L. adecarboxylata* was reported.[57]

Leminorella species.

The genus *Leminorella* contains *L. grimontii*, *L. richardii*, and possibly a third unnamed species.[2] Most human isolates have been recovered from feces and urine. The role of these organisms as primary human pathogens is unclear, but several healthcare-associated infections have been reported, including urinary tract, skin and soft tissue, and surgical site infections, as well as bacteremia and peritonitis.[6,58,59] In one study, *Leminorella* isolates were variably susceptible to antibiotics, including the extended-spectrum cephalosporins and β-lactam/β-lactamase inhibitor combinations; imipenem and amikacin showed the most activity.[58] *Leminorella* isolates harboring extended-spectrum β-lactamases also have been described.[60]

Moellerella wisconsensis.

The genus *Moellerella* contains one species: *M. wisconsensis*.[2] Isolates have been recovered primarily from stool and mainly from people in the state of Wisconsin, including patients with diarrhea, but the enteropathogenicity of *Moellerella* is not clear.[61] Of the few reports of *Moellerella* infections, most were isolated from patients with acute cholecystitis.[61,62] Additional isolates were recovered from blood, bronchial aspirates, and wounds.

Photorhabdus species.

The genus *Photorhabdus* consists of at least three species, but only *P. asymbiotica* has been isolated from humans.[2] *Photorhabdus* spp. live symbiotically in the intestinal lumen of various nematodes and can infect insects. Colonies can have a yellow pigment and are bioluminescent when viewed in a darkened room.

Human infection with *P. asymbiotica* typically involves a primary skin focus (e.g., subcutaneous nodule, ulcer, wound) .[63] *Photorhabdus* organisms have been isolated from soft tissue abscesses, skin biopsies, blood, and sputum. Some infections have relapsed and required prolonged antimicrobial therapy.[63,64]

Rahnella species.

The genus *Rahnella* consists of one primary species, *R. aquatilis*, and at least two additional genospecies.[65] *R. aquatilis* is found in the environment primarily in water.[66] In humans, *R. aquatilis* has been isolated from blood, urine, a burn wound, and a bronchoalveolar lavage specimen. Most infections occur in patients with immunocompromising or other chronic medical conditions.[66] *R. aquatilis* septicemia in a premature infant has been reported.[67] Rahnellae produce β-lactamases but usually are susceptible to extended-spectrum cephalosporins and other antibiotic classes active against Enterobacteriaceae.[66]

Tatumella species.

The genus *Tatumella* is closely related to *Pantoea*.[68] Until recently, only *T. ptyseos* was described in human specimens, but a new species isolated from a patient with cystic fibrosis was reported with the proposed name *T. saanichensis* sp. nov.[69] Most human isolates are from the respiratory tract, but a few have been from BSIs.[70,71] A *T. ptyseos* isolate resistant to imipenem was recovered from an intravenous central line in an adult.[70]

Trabulsiella species.

The genus *Trabulsiella* contains *T. guamensis* and *T odontotermitis*.[72,73] *Trabulsiella* resembles *Salmonella* spp. biochemically because it is positive for hydrogen sulfide production and lysine and ornithine decarboxylase activity (arginine varies). *T. guamensis* has been recovered from soil and human stool, but its clinical significance is unknown.[73]

Yokenella regensburgei.

Y. regensburgei, formerly called *Koserella trabulsii*, is biochemically similar to *H. alvei* but is citrate positive.[74] In the environment, *Y. regensburgei* has been isolated from well water, salads, insects, and reptiles.[75] Rare reports of *Y. regensburgei* infections in adults include BSI, suppurative arthritis, and skin and soft tissue infection.[75,76] *Y. regensburgei* also has been isolated from sputum, urine, and feces.[77]

Acknowledgments

The authors acknowledge the substantial contribution of K.I. Koranyi and M.J. Marcon to this chapter in previous editions.

Key Points

Less Commonly Encountered Enterobacteriaceae

Microbiology

- Advances in molecular diagnostic techniques have identified new species of Enterobacteriaceae that were previously classified as atypical members of other recognized species.

- Susceptibility testing should produce reliable in vitro results for these strains when standardized methods are used.

Epidemiology

- Some organisms are known to cause human infections (e.g., *Edwardsiella*), whereas the roles of other organisms are unclear (e.g., *Trabulsiella*).

- Many published reports have described infections in those with immunocompromising or chronic medical conditions, although infections can occur in previously healthy people individuals.

Clinical Manifestations

- A wide range of clinical manifestations for these species has been described, often limited to case reports.

Treatment

- Optimal treatment varies by species and should be based on susceptibility testing and clinical considerations, including agents and regimens typically used against Enterobacteriaceae.

- Isolates of some species harbor resistance genes such as *ampC* (e.g., *Cedecea*), extended-spectrum β-lactamases (e.g., *Leclercia*), and carbapenemases (e.g., *Kluyvera*).
